Dr. D. F. McMichael, curator of molluscs, the Australian Museum, Sydney, to assist him to spend about four months from October 1961 at the British Museum (Natural History) studying the collections of molluscs with special reference to the type specimens of Australian and New Guinea land and freshwater molluscs housed there.

Dr. W. Macnae, lecturer in zoology, University of the Witwatersrand, to enable him to spend 6–8 months from December 1961 based on the University of Queensland and studying the ecology of the *Cymodocea* fields and mangrove swamps on shores within the Great Barrier Reef and in northern Australia.

Dr. J. N. Phillips, of the Commonwealth Scientific and Industrial Research Organization (Australia) Division of Plant Industry, Canberra, to enable him to extend his physico-chemical studies on plant and animal pigments at Imperial College of Science and Technology, London, for about eleven months from December 1961.

Dr. Muriel L. Tomlinson, university demonstrator in organic chemistry, Oxford, to enable her to study polydentate compounds at the University of Sydney for about three months early in 1962.

Prof. D. Walker, professor of physics, Victoria University of Wellington, to enable him to make a study of experimental research work at present of interest to workers with low-energy Van de Graaff accelerators (or similar machines), and to study the working of the National Institute for Nuclear Science in Britain, for eight months from June 1962.

Dr. H. B. S. Womersley, reader in botany, University of Adelaide, to assist him with maintenance costs at Vancouver for three months from April 1962 while making ecological comparisons of the intertidal biology (especially marine algae) of southern Australia and the western North American coast.

Announcements

Sir Howard Florey, president of the Royal Society and professor of pathology in the University of Oxford, and Dr. Owen H. Wangensteen, chairman of the Department of Surgery, University of Minnesota, and formerly president of the American College of Surgeons, have been elected Honorary Fellows of the Royal College of Surgeons of England.

Mr. G. C. Tootill (Royal Aircraft Establishment, Farnborough) has been appointed chairman of a special committee to consider international standards work on information technology by the International Federation of Information Processing Societies.

An international conference on elementary particles will be held during September 14–20 at Aix-en-Provence, France. Further information can be obtained from the Scientific Conference Secretariat (E. W. D. Steel), CERN, Geneva, 23, Switzerland.

The Technical Section of the British Paper and Board Makers' Association is organizing a conference on "The Formation and Structure of Paper", to be held at the Dyson Perrins Laboratory, Oxford, during September 25–29. Further information can be obtained from the Technical Section, British Paper and Board Makers' Association, St. Winifred's, Welcomes Road, Kenley, Surrey.

Under the auspices of a committee appointed by the Conchological Society of Great Britain and Ireland and the Malacological Society of London, the first European Malacological Congress is to be held in London during September 17–21, 1962. The object of the Congress is to discuss all aspects of European Malacology and the formation of a European Malacological Union. The Congress is open to all interested in Malacology, and further information can be obtained from the honorary secretary, Rev. H. E. J. Biggs, 19 Siward Road, Bromley, Kent.

The Institute of Physics and the Physical Society and the British Radio Spectroscopy Group are jointly holding a two-day conference on "Radio Spectroscopy of Solids" in the Department of Physics, University College of North Wales, Bangor, during September 21–22. The Institute and Society's Guthrie Lecture will be presented during the conference by Dr. D. Shoenberg, who will speak on "The de Haas–van Alphen Effect and the Electronic Structure of Metals". Further information can be obtained from the Administration Assistant, The Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

Errata. In the review of Prof. Fraenkel's *Abstract Set Theory* (*Nature*, June 17, p. 1047) the publisher was given as Elsevier Publishing Company, of Amsterdam. This should have read North-Holland Publishing Company, Amsterdam.

In the report on the Arthur D. Little Research Institute (*Nature*, 190, 1068; 1961), five lines from the end, for 'acid' read 'non-acid'.

SHORTAGE OF MATHEMATICS TEACHERS IN BRITAIN

A QUESTION was asked by Lord Boothby in the House of Lords as to whether, having regard to the essential part played by school mathematics in the training of scientists and technologists, and in view of the present shortage of more than 3,000 mathematical teachers in British schools and the fact that replacements were not matching retirements, the Government now proposes to take action to avert the incipient disintegration of technological training in Britain.

In replying on June 7, Lord Hailsham said that the Government has already taken action to meet the serious shortage of mathematics teachers in the schools, which it recognizes to be a matter of serious concern. He did not accept Lord Boothby's conclusion. The grave shortage of mathematics graduates able and willing to teach has been made known to the university authorities, and consultations are taking place with them about how the problem could best be tackled. The Minister of Education has also taken measures to improve the supply of non-graduate teachers of this subject.

Lord Boothby then referred to action taken by the National Science Foundation in the United States, of which full details had been given to Lord Hailsham, and to the recommendations of the Mathematics Conference at Southampton last April; but Lord Hailsham insisted that the core of the problem is the provision of graduates and that this is the province of the universities. As regards non-graduate teachers, the provision of a three-year as distinct from a two-year course has enabled the Minister of Education to raise the standard in teacher-training colleges. Lord Hailsham promised to note Lord Boothby's suggestion about better co-ordination between the Ministry of Education, his own Ministry, the University Grants Committee and the universities. He believes that there are difficulties in Baroness Summerskill's suggestion of a special financial premium for those teaching science and mathematics, and in reply to Lord Alexander of Hillsborough said that the anxiety of parents in relation to the present teaching of mathematics is not well founded. One factor in the shortage is the whole range of new opportunities now open to mathematics graduates. What is really wanted is an increase in the total output of graduates, and he is not satisfied we have as yet exhausted the potentialities of mathematical ability. He said that personally he is not satisfied that the methods of teaching mathematics could not be improved, so as to attract some who had hitherto been repelled. He thought that the shortage of mathematics teachers is likely to become, and is already, very much worse than the general shortage of teachers.

In a written answer in the House of Commons on June 13, the Minister of Education said that as a result of his Department's request to training colleges to give greater prominence to mathematics, the annual number of students reading mathematics as a main subject has risen from 770 in 1955–56 to 1,650 in 1960–61. The three-year course should greatly help to raise academic standards, and the colleges should then be sending forward to the primary and secondary schools more and better teachers of mathematics. He expected the numbers to rise further with the expansion of the colleges. The colleges are also providing one-year courses for substantial numbers of serving teachers, and various other shorter courses are also available for serving teachers and members of mathematics staffs in the training colleges. Advanced courses in the technical colleges leading to a degree or diploma in technology are also being expanded. The main problem is the shortage of mathematics graduates, particularly those able and willing to teach. Mathematicians in schools and universities had been actively discussing the question and canvassing possible solutions. He said he has made sure that the gravity of the shortage and the need for action are known to the university authorities. His Department has been working for some months with the Teachers' Advisory Council, and the universities have been approached through the Vice-Chancellors' Committee. It is proposed to hold a conference at an early date under university auspices to examine the evidence collected and consider possible action, and Sir David promised to bear in mind the suggestion of a White Paper.

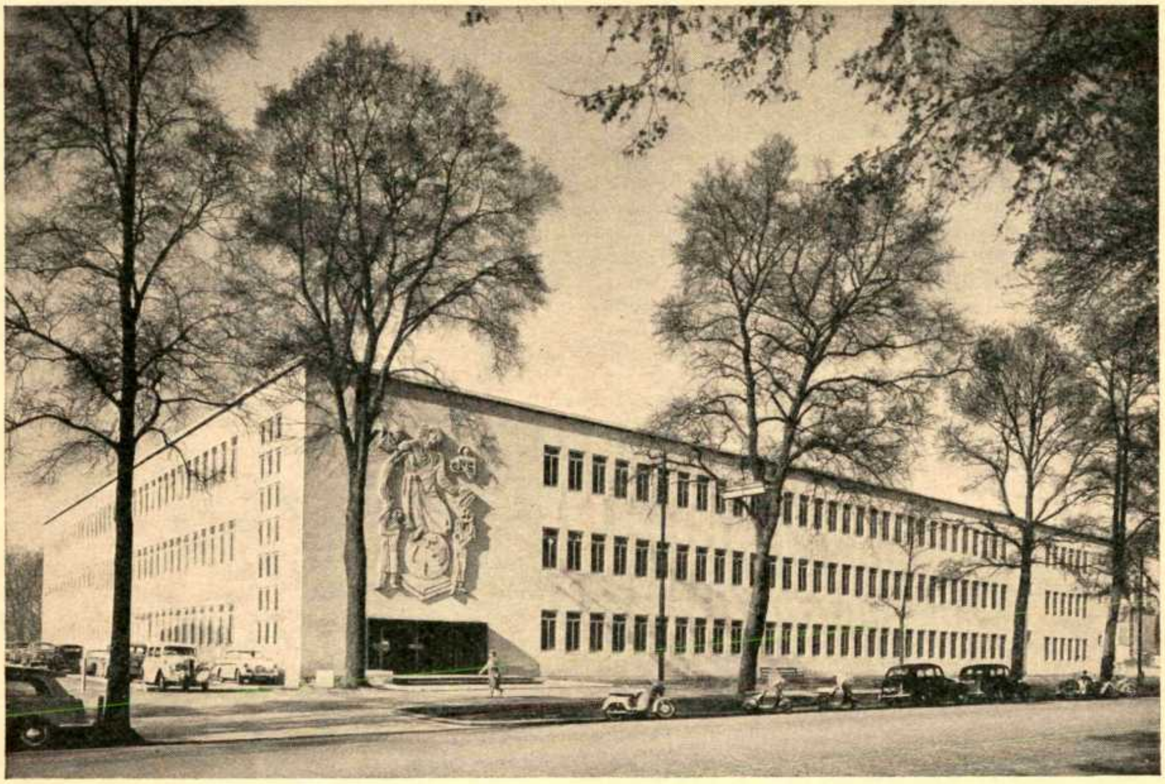
It might be noted here that in the House of Commons on June 8, in replying to a question about difficulties anticipated in recruiting scientific staff for the universities expansion programme, Sir Edward Boyle said that the increase in recent years of the number of Department of Scientific and Industrial Research postgraduate training grants—from 979 in 1958 to 1,259 in October 1960—would contribute materially to the supply of potential teachers. Besides considering representations about a further salary revision, the University Grants Committee is at present giving particular attention to the provision of adequate facilities for university staff, both for teaching and research (see also p. 103 of this issue).

THE WELSH COLLEGE OF ADVANCED TECHNOLOGY

By Dr. A. HARVEY
Principal of the College

AN additional building for the Welsh College of Advanced Technology, situated in Cathays Park, Cardiff, was formally opened by H.R.H. The Duke of Edinburgh on June 2, the ceremony forming part of the Welsh programme for Commonwealth Technical Training Week. The building re-houses the three Departments of Chemistry and Biology, Navigation and Pharmacy. It also provides much improved amenities for the College as a whole, including a refectory, great hall, senior common room and a self-contained Students' Union suite.

The architect was Sir Percy Thomas, who was also (in conjunction with Mr. Ivor Bishop) responsible for the main building of the College, which was com-



[Photo: Hylton Warner

Fig. 1. Extension of the Welsh College of Advanced Technology

pleted in 1916. The college buildings are about 100 yards apart, being separated by the Temple of Peace, for which Sir Percy was also the architect (1938). The main contractors were Messrs. J. Gerrard and Sons, Ltd., of Swinton, the cost of the building being £626,724, and that of the furniture £66,600. The equipment, most of which is now installed, is costing approximately £150,000.

The structure is steel-framed and the exterior faced with Portland stone, so as to harmonize with the other buildings in the Civic Centre. The floors were made from pre-cast concrete units and have a variety of finishes, depending on the use to which a particular room is put. It is worth noting that the use of battleship lino in the corridors has largely eliminated the noise problem often encountered. All the usual services, including compressed air, steam and vacuum, are available, housed either in ducts or above the ceilings, and the layout of the services is such that any non-laboratory type of room can, when necessary, be converted into a laboratory. A goods lift is available for heavy or bulky supplies, and there are small electrically operated hoists in the science departments. Thus bulk supplies are received on the ground-floor and distributed from there, as required, to store rooms on the upper floors.

The Department of Chemistry and Biology occupies the three floors comprising the east side of the building, and its accommodation includes ten main laboratories with ancillary balance and preparation rooms. There are four research laboratories and two lecture rooms. The specialized provisions worth noting are for polymer chemistry and technology (two laboratories, a flame-proof room and workshop for the preparation and testing of plastics and rubber products) and for work with radioisotopes (laboratory, counting room, dispensary and an underground store).

Before the War this Department was well known as a research centre and during the late 1930's eight students obtained the Ph.D. degree, four the M.Sc. degree. Now, after a rather lengthy break, research is developing once more. Work in progress at present includes a series of studies in polymer chemistry and technology dealing with rubber vulcanization, rubber mastication, molecular shapes of polypropylene glycols and viscoelastic properties of epoxide resins. Other work includes a theoretical study of counter-current extraction, electrolytic dissociation, uptake of fall-out products by lower plants and studies of vitamin C deficiency.

Because of the importance attached to the education and training of industrial chemists, special attention has been paid to instrumental analysis. A wide range of instruments, including ultra-violet and infra-red recording spectrophotometers, is housed in an instrument room, equally available for instruction and research. In addition to this a laboratory has been equipped for the ultimate analysis of organic compounds.

The Welsh School of Pharmacy occupies the whole of the three floors forming the south side of the building. It thus has available some 21,000 sq. ft. of accommodation which includes sixteen teaching laboratories, eight research laboratories, together with nineteen other rooms (lecture rooms, stores, preparation rooms, etc.). The largest lecture theatre will seat 150 and has been so sited that it can be used, in conjunction with an adjacent committee room and cloakroom, as a self-contained suite available for professional bodies and societies.

This Department is responsible for the education and training of pharmacists who may enter hospitals, industry or retail work. The College is affiliated, in respect of this work, to the University of Wales, so that students can take either the B.Pharm.(Wales) or the pharmaceutical chemist qualifying course. The Department has been designed for an annual intake of 64 students for a three-year course, but this could be increased to 96 without much difficulty.

The Department is an active research centre and is recognized by the University as a place for research for M.Pharm., while application has been made for recognition for Ph.D. There have now been seven M.Pharm. awards to members of the College.

Research at present in progress in the Department includes: physico-chemical studies on phosphatides; kinetics of the bromination of phenolic aldehydes; synthetic studies on rotenoids; synthesis of 2 : 2 dimethylchromenes which may have physiological activity; synthesis of apomorphine derivatives; synthesis of sulphones as antibacterials; properties of liquorice and its constituents, with particular reference to its value as a pharmaceutical excipient; control and prediction of particle size in ball milling; conductance of emulsions; effect of moisture on porcelain dental fillings; chromatographic techniques applied to crude vegetable drugs; pharmacology and biochemistry of substituted glutarimides; cotton dust and other vegetable dusts in relation to byssinosis; macrocyclic compounds related to steroid hormones; action of bases on chloroform; transformation of glycyrrhetic acid; changes in drug sensitivity in states of avitaminosis.

The Navigation Department occupies the bulk of the two upper floors above the Students' Union. Apart from a small amount of part-time work for yachtsmen, its function is the preparation of serving merchant navy officers for Ministry of Transport Certificates of Competency. It is exceptionally well equipped, as befits the only Navigation Department in a College of Advanced Technology. One special feature is an instrument room, which houses all the aids, electronic or otherwise, which an officer might find on the bridge of a modern merchant ship. A radar simulator (costing £12,000) is now being installed, and this will supplement the training given in the College Radar School at Cardiff docks. Another interesting feature is an extremely compact demonstration set-up, where twenty students can sit around the working bench with not one of them more than 6 ft. from the demonstration.

The communal facilities in this new building include a refectory, kitchen, etc. Above this, and extending through the two upper floors, is the Great Hall. Measuring 80 ft. × 60 ft., this hall, with its gallery, can provide seating for nearly 800. It has a large stage, fully equipped, with ancillary stores and storage space, and two dressing-rooms. A large window at the back of the gallery enables the classroom behind it to be used as a control room for radio and television programmes. Access to the building is arranged in such a way that the great hall can be used without interfering with the rest of the building. The meetings of the British Association for the Advancement of Science, 1960, saw the first use of the Hall, and a number of exhibitions have already been held in it, including one staged by the United Kingdom Atomic Energy Authority.

Finally, reference must be made to the Students' Union. This is a self-contained suite of rooms of some 5,000 sq. ft. and the accommodation includes two lounges, two recreation rooms, a council room, chapel, a music room, a photographic room, together with various offices for the conduct of Union business. Although the Union has always been a very live body, the improvement in facilities has already resulted in a marked development of student activities.

GAS-PHASE REACTIONS OF THE HALOGENS AND THEIR COMPOUNDS

An informal discussion on "Mechanisms of the Gas-Phase Reactions of the Halogens and their Compounds" was held on March 28 at University College, Cardiff, under the auspices of the Faraday Society. About seventy members and guests were present. The chairman of the first session, Prof. A. G. Evans (Cardiff), welcomed the visitors to Cardiff and introduced the foreign guests. Dr. P. G. Ashmore (Cambridge) then reported further investigations in his detailed study of the pyrolysis of nitrosyl chloride. He showed that the addition of nitrogen dioxide to nitrosyl chloride leads to a fast but rapidly inhibited decomposition. The catalysis was explained by postulating the intermediate formation of nitryl chloride, that is :

$$NOCl + NO_2 \xrightarrow{12} NO_2Cl + NO$$

$$NO_2Cl + M \xrightarrow{14} NO_2 + Cl + M$$

$$NO_2Cl + NOCl \xrightarrow{15} NO_2 + NO + Cl_2$$

The auto-inhibition was explained by reaction of the product nitric oxide with nitryl chloride :

$$NO + NO_2Cl \xrightarrow{13} NO_2 + NOCl$$

Estimates were given for k_{14} with $M = NO_2$ and N_2 and new values had been obtained for k_3 in the reaction :

$$NOCl + M \xrightarrow{3} NO + Cl + M$$

with $M = NOCl$, NO, N_2 and H_2. One surprising feature of these last results was the very small differences found for the activation energies and pre-exponential factors when M was varied.

The second paper by Prof. R. G. W. Norrish (Cambridge) gave an account of the flash photolysis of nitrosyl chloride in the presence of a large excess of inert gas to ensure isothermal conditions. Many absorption bands were produced in the region 2100–4000 Å. The conditions of the experiments were such that the light causing photolysis was mainly in the region below 2700 Å. Since the N—Cl bond in NOCl has a dissociation energy of approximately 38 kcal., this corresponds to an excess energy of 70–110 kcal. (at the limit of transmission of quartz). The absorption bands in the spectrum that follows the flash have been assigned to transitions from the ground-state of NO ($X^2\pi$) to excited states $A^2\varepsilon$, $B^2\varepsilon$, $C^2\pi$ and $D^2\varepsilon$, and it was demonstrated that all vibrational levels of the ground-state up to $v'' = 10$ were populated.

Norrish was able to show that at least 50 kcal. of the excess energy of the flash appears as vibrational energy in the nitric oxide molecule, and suggested that this occurs in the primary process, namely:

$$NOCl + h\nu \rightarrow NO^* + Cl$$

Various other possibilities were discounted on energetic or theoretical grounds.

Finally, he suggested that such a process may have a fairly wide generality, and could explain the production of many of the highly vibrationally excited molecules produced in flash photolysis.

Dr. J. H. Thomas (Cardiff) then discussed the gas-phase reactions of methyl chloride, methylene chloride and chloroform with nitrogen dioxide. He showed that the reactions were autocatalytic in nature, and led to complex oxidation products. Two of the products, hydrogen chloride and nitrosyl chloride, had marked catalytic effects when added to the initial reactants, as did the addition of chlorine. He suggested that the autocatalysis resulted from the production of chlorine atoms by reactions such as:

$$HCl + NO_2 \rightarrow Cl + HNO_2 \quad (1)$$

and

$$NOCl \rightarrow NO + Cl \quad (2)$$

followed by hydrogen abstraction by the chlorine atoms, for example:

$$CH_3Cl + Cl \rightarrow CH_2Cl + HCl \quad (3)$$

The final products were explained by a mechanism involving further reactions of the radicals produced in (3). The reactions of the three chloromethanes were compared, and it was explained that carbon tetrachloride was unreactive until much higher temperatures were reached.

In the second session, with Prof. R. G. W. Norrish in the chair, two papers on aspects of the photochlorination of chlorinated ethylenes were presented by Prof. F. S. Dainton (Leeds) and Prof. P. Goldfinger (Brussels). These reactions all involve chains initiated by chlorine atoms via :

$$A + Cl \underset{2}{\overset{1}{\rightleftharpoons}} ACl$$

where A is an olefine. The radical ACl finishes in the main as ACl$_2$ and various chain-termination steps may occur. Both groups of workers used experiments with intermittent light to find the Arrhenius parameters for the various chain steps.

Dainton has studied the olefines $C_2H_nCl_{4-n}$, $n = 0$–4, with the exception of vinylidene chloride. Reaction (1) is very exothermic for these olefines, hence the ACl radical should have considerable energy and may be regarded as an excited molecule ACl*. The Arrhenius parameters for reaction (2) should then be quite different from those for the decomposition of a normal ACl radical. This was found to be so for A = vinyl chloride, where $E_2 = 0{\cdot}7$ kcal. mole^{-1} compared with $E_2 = 22{\cdot}0$ kcal. mole^{-1} from pyrolysis studies.

Goldfinger has studied trichloroethylene to find out if reaction (1) above gives the symmetric ($\dot{C}Cl_2.CCl_2H$) or asymmetric ($CCl_3.\dot{C}HCl$) radical. The method used involved the photochlorination of trichloroethylene in the presence of either sym. or asym. tetrachloroethane (since hydrogen abstraction by chlorine atoms from the last two substances will give the sym. and asym. radicals referred to above). An analysis of the kinetics of the reactions of these mixtures showed that reaction (1) gives the sym. radical, that is :

$$CHCl = CCl_2 + Cl \rightarrow CHCl_2 - \dot{C}Cl_2$$

The activation energy for the reverse of this reaction was found to be 19 kcal. mole^{-1}, which is much larger than the value of 6·6 kcal. mole^{-1} found by Dainton for the same reaction. Goldfinger was unable to find evidence of the formation of excited ACl radicals.

After lunch, Prof. E. C. Kooyman (Leyden) was chairman and the first speaker was Dr. E. Whittle (Cardiff), who described the photosensitized brominations of methanol, ethanol, formaldehyde and acetaldehyde. The main purpose of these investigations was to obtain information about the strengths of certain of the bonds in the molecules. The products of the reaction were identified and explained in terms of chain reactions involving bromine atoms. Dr. Whittle discussed in detail the photobromination of methanol and its kinetics under varying conditions, which resulted in different chain termination processes. The reaction $Br + CH_3OH \underset{2}{\overset{1}{\rightleftharpoons}} CH_2OH + HBr$ was found to have an activation energy E_1 = 6 kcal. mole^{-1}. This gives $\Delta H_1 \leqslant 4$ kcal. mole^{-1} and hence $D(H{-}CH_2OH) \leqslant 92$ kcal. mole^{-1}. The CH bond in methanol is thus considerably weaker than in methane, for which $D(H{-}CH_3) = 102$ kcal. mole^{-1}.

Dr. J. M. Tedder (Sheffield) then discussed the fluorination, chlorination and bromination of the butanes and normal and secondary butyl halides. For unsubstituted butanes the activation energy for abstraction of hydrogen atoms by different halogen atoms are of the order : fluorination 100 cal. mole^{-1}, chlorination 1,000 cal. mole^{-1}, bromination 10,000 cal. mole^{-1}. In all cases the activation energies decrease for different hydrogen atoms in the order tertiary < secondary < primary.

The introduction of substituent halogen atoms into butane has a considerable effect on the rates of halogenation of sites adjacent to the substituent. The previously accepted assertion that a substituent halogen atom directs attack by chlorine atoms away from itself was shown to be incorrect, for example, in the chlorination of 2-chlorobutane the dichlorobutane formed in the largest amount was 2.2-dichlorobutane. For brominations similar effects were found, but in the fluorination of 2 halobutanes only slight attack occurs at the 2- position. The experimental results were interpreted in terms of the Evans and Polanyi picture of the transition state.

The final session with Prof. F. S. Dainton in the chair was opened by Prof. Kooyman, who described the results of a study of the products of the chlorination and bromination of aromatic materials in the gas phase. Chlorinations were carried out at temperatures between 300°–450° C. and brominations between 400°–500° C. Typical reactions were between bromine or chlorine and diphenyl ether, fluorobenzene, chlorobenzene and benzonitrile. The striking feature of all these reactions is that substitution occurs with major products being the meta-isomers. This is in complete contradiction in all cases to liquid-phase halogenations where *ortho/para* substitution predominates.

Kooyman said that a radical mechanism alone could not readily explain the specificity of the results obtained and put forward the novel suggestion that the reactions occurred through an ionic intermediate, that is :

$$X_2 \rightarrow 2X$$
$$X + \mathrm{ArH} \rightarrow [\mathrm{ArH}^+][X^-]$$

A proton is then lost from the position with highest positive charge, that is, the *meta* position :

$$[\mathrm{ArH}^+][X^-] \rightarrow \mathrm{Ar} + \mathrm{H}X$$
$$\mathrm{Ar} + X_2 \rightarrow \mathrm{Ar}X + X$$

This mechanism provoked a lively discussion, and the outcome of Prof. Kooyman's present work on the kinetics of these reactions is awaited with interest.

Finally, Dr. B. A. Thrush (Cambridge) described spectroscopic studies of bromine atom recombination. The studies employed the technique of flash photolysis to study the recombination of bromine atoms in excess argon to determine whether the bromine molecules formed in the recombination are produced in an electronically excited state or with excess vibrational energy. No evidence for the former was found but absorption spectra obtained during the recombination showed an appreciable increase in the population of the lower excited vibrational levels of the ground-state, notably $v'' = 1,2,3,4$ and 5.

The distribution of this energy corresponded to temperatures much higher than those to be expected from the amount of energy absorbed from the flash.

The papers presented stimulated a lively discussion throughout and thus ensured the success of the meeting.

E. Whittle

AUTHOR AND PUBLISHER

PROBLEMS arising in connexion with the publication of scientific books were discussed at a recent meeting of the Scientific Publications Council held at the Ciba Foundation, London. Prof. G. W. Harris was in the chair.

Mr. David Dickens (Pitman Medical Publishing Co.) said that the publication of scientific books is not a lucrative business. Scientific books are generally written for the specialist, and consequently the market for them is small. A publisher of scientific text-books must maintain a staff of highly qualified editors and sub-editors, generally with science degrees, who work together with the authors to get the manuscripts into shape for publication. This is often a long process involving heavy investment: one book alone might cost £4,500 to produce and may take many years to bring back the outlay. The publisher contributes, as indicated by his 'imprint', prestige, knowledge of the field and 'know-how'. He has the same interest as the author in getting a book published as quickly as he can.

Ownership of Copyright

Mr. Dickens stated that the copyright is the author's as soon as he puts pen to paper. The publisher is generally better able to deal with selling the rights than the author, and he should do this in the author's name. Difficulties may arise if a book is written by joint authors who later decide to part. Mr. D. M. Neale (Oxford University Press) believed that it is often more convenient for the publisher to hold the copyright in order to protect the author's interests, although this is not necessarily a good general rule. His firm has been taking legal action to stop a book being pirated in Hong Kong: it could not have done this if the copyright were in the author's name, since the author was in Europe doing research. The cost of fighting an action of this kind is enormous and is all borne by the firm. When an institute publishes a series of volumes, the copyright is sometimes held by the institute: otherwise the Oxford University Press prefers to keep the copyright and return to the author whatever they may get from sale of the rights. Difficulties can arise if a publisher holding the copyright is taken over by another firm: the author has generally no defence against that. Miss M. E. Barber (Society of Authors) said that some publishers never take the copyright, but others do claim it, often in the first clause of the contract. The copyright includes translation, broadcasting, television, film, drama, digests and paperback editions. The Society of Authors takes the view that the publisher does not need the copyright: he should negotiate the rights as the author's agent. Scientists often regard writing as a side-line, and they do not take the trouble they should over contracts: publishers therefore treat scientists in a way in which they would not treat other authors. Only if piracy were rife enough to be an overriding consideration would it be justified for the publisher to hold the copyright.

Mr. A. L. Bacharach (Nutrition Society) said that the author of a paper in a scientific journal is in a different position from the same author when writing a text-book. The copyright of a scientific paper is owned by the author, unless he has specifically assigned it to a body, such as a learned society: but recently it has been suggested that the copyright of a paper belongs to the employer of the author. Dr. E. A. Moelwyn-Hughes (Cambridge) said that some countries still take no notice of copyright. When in the U.S.S.R. he had discovered by chance that 20,000 copies of a book by him had been distributed there, but he had received no royalties from the Russians. He had heard that there was also a Japanese edition, from which he also had no royalties. It is generally understood that an author can quote material from another publication so long as he gives the source and reference, but some publishers object to this. What is the legal position ? Miss Barber replied that quoting from another publication is often done by scientists, but it is an infringement of copyright to quote "a substantial part" of a copyright work without permission. Even summarizing a publication of another author or publishing an abstract is an infringement of copyright if done without permission.

Contractual Relationships

Prof. G. V. R. Born (London) said he knew of scientists who had experienced difficulties with their publishers. How can scientists be warned about publishing difficulties ? Contracts often contain an arbitration clause which may delay decision in disputes; would it be better for authors if there was no such clause? Can a publisher be asked for an audited account? Miss Barber said that an author is entitled to detailed royalty statements and that, if he had good reason to doubt their accuracy, he had a common law right to inspect the publishers' books of account, though this was a little cumbersome to enforce. The name of an unreliable firm cannot be published openly or broadcast; but a name can be omitted from a list of recommended firms. Mr. Bacharach said that the good publisher presents no difficulty: contracts are necessary, because there are bad publishers who try to manipulate an agreement to the author's disadvantage. Sometimes contracts contain a clause giving the publisher the right to call on the author to prepare a new edition; they should include also a clause requiring the publisher to let the author make such revisions as he may wish to a new issue. This is particularly desirable in scientific broadcasting; the B.B.C. has agreed that there should be no repeat after six months without giving the author a chance to revise.

Dr. Moelwyn-Hughes referred to an eminent scientist who had been cheated by a publisher. Something needs to be done in the scientific world to combat the recent development of mushroom firms that are financially slick and trade on the business incompetence of the scientist. Dr. D. Richter (Carshalton) said that British publishers have built up a high reputation in the past, so that authors have come to trust their publishers as they would their doctors or solicitors, but recently publishers of a different type, interested mainly in quick profits, have entered the scientific field. There have been instances when the publisher has sold rights without informing the author, when inaccurate royalty statements have been given and when scientists have received no royalties at all from sales of their books. Unfortunately the reliable old-established firms tend to be slow and do not always appreciate the special requirements of the scientist. The mushroom firms are exploiting the good faith of the scientific writer and giving British publishers a bad name. Prof. G. W. Harris said there is a need especially for the younger scientists to be informed of the situation.

D. Richter

SOUTH-EASTERN UNION OF SCIENTIFIC SOCIETIES ANNUAL CONGRESS

At the invitation of the Haslemere Natural History Society and the management committee of the Educational Museum, the South-eastern Union of Scientific Societies held its sixty-sixth annual congress at Haslemere during May 26–28, under the presidency of Prof. S. W. Wooldridge. The Council's choice of the theme for the congress of "The Changing Countryside" proved successful, allowing the lecturers full freedom in the presentation of their subjects and of focusing attention on the need for preservation and the desirability of intelligent management in Nature conservation. The delegates were welcomed by Dr. Rolston, chairman of the management committee of the Museum.

The young naturalists' evening included a brains trust with questions answered by a panel of experts, under the chairmanship of Maxwell Knight, followed by the screening of a film "Journey into Spring", introductory to the visit to Selborne.

The presidential address was given by Prof. S. W. Wooldridge, whose subject was "The Land and Man in the Western Weald". He commenced by emphasizing that, although the land existed before man, it was not an environment until man entered on it and reacted to it. The notion that the Weald is a denuded simple anticline has existed for some 150 years, from the time of John Fairey, who also introduced the use of the term 'denudation'. His observations of the area were made from the top of a stage-coach in the days of leisurely travel. It is now known that between the south coast and the Thames valley there are six anticlinal crests, somewhat resembling corrugated iron in form. For convenience of understanding, Prof. Wooldridge defined the country west of Stane Street as the Western Weald, wherein the Hythe Beds suddenly expand to form a major feature. It was important to remember that at one time the Chalk stood 2,000–2,500 ft. above the present land-level near Haslemere. Dealing with the influence on subsoil and soil types, it was pointed out that the intermediate and loamy soils are not derived from one particular formation, but have different soil parents. Our ancestors chose the Upper Greensand at the base of the chalk as good growing land, the best arable ground. It should be remembered that the dry valleys were not dry even in Romano-British times. Prof. Wooldridge next dealt with the succession of occupants. During Mesolithic times, about 6,000 B.C., when the climate was wetter than at present, the area on the Surrey–Sussex border was occupied. Evidence of man's later activities, during Neolithic times, had been found in the ditches at the Trundles. The following early Bronze Age had the same type of life and culture, and it was not until the late Bronze Age that the real cultivation of the land began. There is evidence of industry and trade during the Iron Age, 500 B.C.; the so-called hill forts are really the beginnings of cities on the hills. A later stage was the creation of the village communities, about A.D. 600, located by the early Saxon place-names, often those of pagan deities. The last stage is indicated by the distribution of the Domesday vils, the parish boundaries showing a remarkably even pattern, especially along the edge of the Tertiary beds.

The zoological section was addressed by John Sankey, on "Invertebrate Life in South-east England". He has for 14 years been fighting a campaign for greater investigation of the lesser-known invertebrate animals. The butterflies and beetles had been studied well enough, but such groups as centipedes and spiders need far more attention, especially observational work on their life-history and ecology.

Unless this can be done now, the changing countryside will eliminate them before they can be studied. Foam, muck and dirt are polluting many of their habitats. Specimens of the lesser-known invertebrates do not make a great display, but the need is for the collection of information rather than of specimens. Information is especially required of the habits of the fresh-water sponge, flat worms, millipedes, spiders and molluscs; the life-cycles of many are not known. The only locality in the south-east of England for the raft spider is at Frensham bogs, and it would be a great pity if the area is drained, causing its extinction. Mr. Sankey emphasized the necessity for a true understanding of conservation, not by leaving areas alone, but by proper management by people who know what they are doing.

The address to the botanical section was given by J. E. Lousley on "The Changing Flora of South-east England". He said that conditions are changing constantly and rapidly, but all changes are not necessarily bad; things need not always remain as they were when one was young. In a progressive world one must be progressive, and it is well to remember that the quarries and sandpits excavated by our grandfathers are now some of our best habitats. There was considerable upheaval by the building of railways, but there has been good recolonization of the railway embankments. The canals, many of which are now abandoned, are rich in aquatic plants, some of which had been introduced by the barges, and the filled-in canals provide habitats for many species. The greatest losses have been through building extensions; that around London has destroyed many habitats, while drainage has reduced the number of boggy areas. The indiscriminate dumping of rubbish is deplorable; the example at Mitcham Common was to be avoided. Changes are to be seen in the village ponds (no longer required for animals), which have now become the receptacles for rubbish. A further undesirable change is brought about by the use of the ground by the Army for tank training, and the carelessness of the public is a constant threat, by fire, on heathlands. Great changes in the vegetation have been brought about by the reduction of grazing and the deplorable elimination of the rabbit, resulting in the vast increase of scrub. It is now necessary for a conservation corps to be constantly clearing the scrub to maintain the survival of the interesting plant life.

The general interest of the public has increased, particularly in the British flora, and this aids the propaganda for the need of preservation and conservation.

Miss Phyllis Bond addressed the delegates on "Birds in a Changing World". The change in south-east England was swifter than in most areas, owing to its proximity to London, increasing greatly since the beginning of the century. The spread of residential building may increase the bird population, gardens providing a variety of habitats, but the occupants are the so-called common birds and the need is to provide suitable habitats for the rarer species in danger of elimination. One of the hazards of progress is that a large part of the resident population is not indigenous and is always tidying up, thus removing the habitats necessary for some birds. Nature and man have from the earliest times moulded the shape of the countryside, and man's effort is often not to its advantage. Miss Bond regretted the passing of the rabbit; the change in the nature of the herbage has been to the disadvantage of many birds, depriving them of their usual nesting sites and reducing the insect population, which provided their food. She deplored the practice of spraying road-side verges and hedgerows with poisonous compounds, especially between the months of April and August. The shrubs and herbage which were the breeding places of many birds are either killed or starved; there is a chain of deterimental reaction the ultimate result of which cannot be perceived. Poisoned seed is also responsible for much injury, for not only are birds and animals killed by directly taking the seed, but also their food of worms and other invertebrates carries the poison and thus adds to the casualties.

The attitude of the public towards birds has changed for the good; the shooting of birds and the collection of eggs are now regarded as belonging to past generations.

Dr. J. F. D. Frazer, conservation officer for England of the Nature Conservancy, chose as the title of his address, "Problems of Managing Nature Reserves". The Royal Charter granted to the Nature Conservancy included a clause enabling it to acquire and manage nature reserves. Land left alone becomes a wilderness so the principles of management have to be studied and applied. First, the type of nature reserve desired has to be determined, and the drawing up of a management plan is the work of two or three years. The past history of the area has to be studied, its geology, the arrival of man, up to its present state. The climate and existing species have to be studied; it has to be decided what is wished to be done and how it is going to be achieved. In some cases the public can be allowed access without harm being done, but when sand dunes are the subject the public must be kept off. An area may need to be managed correctly, as at Blean Wood, Kent, for the protection of one butterfly or as at Wye for the preservation of an orchid population. The desirability of introducing 'foreign' animals and plants or the re-introduction of those that have become extinct has to be discussed and the good relations with the owner of adjacent property encouraged.

Dr. Frazer showed slides of areas taken from the same point yearly during 1954–60 showing clearly the evil results of the extermination of the rabbit, which controlled the growth of ragwort, gorse and the scrub. Without grazing, the only way to reproduce the former condition is by cutting, and a corps of conservationists is required to work on this, under the direction of a conservation officer, who determines the areas to be cleared, the amount necessary and the regularity of the period of clearance to ensure success. Favourable weather conditions enabled the full programme of excursions to be carried out. The archæologists visited Selborne Priory and church, and a general natural history party after visiting 'The Wakes' at Selborne continued to Nore Hill for the Chalk flora. Botanists and zoologists went to the Juniper Hall Field Centre, Box Hill, and the surrounding countryside for the Chalk flora and invertebrates; particular interest was shown in the trap-door spiders at their only known locality in south-east England.

The excellent arrangements for the congress were undertaken by a local committee with John Clegg as secretary.

The sixty-seventh annual congress of the Union will be held at Colchester during June next year, and it is hoped that the meeting will provide an opportunity to stress the importance of the natural sciences in the curriculum of the new university to be established there.

F. J. Epps

PARASITE BIOLOGY

THE third spring meeting of the Parasitology Group of the Institute of Biology was held at Wills Hall, Bristol, during April 11–13. The meetings were well attended, and a number of visitors from overseas were present. There can be no doubt that this annual meeting held at a provincial centre has become established firmly in the activities of the Group. An important item in the programme was the address by an invited speaker. This item was introduced last year at Liverpool when Prof. T. H. Davey took as his subject "Parasites as Enemies and Allies". It proved a very useful focus of interest, and this year Prof. C. Read was invited to speak. He gave as his title "The Host-Parasite Interface: Molecular Basis of Parasitism". Prof. Read is professor of biology in the Rice Institute, Houston, Texas, and is at present on sabbatical leave working at the Molteno Institute, Cambridge. He began by discussing parasitism as part of a broad definition of 'symbiosis' considered as a function of the intensity of the field of association established between organisms, and of the internal and external resistances surmounted in its establishment. The parasite comes to depend on the host for the maintenance of homeostasis, and the regulation of homeostasis of a parasite intimately involves a region in space and time which can be designated 'the host-parasite interface'. The host, however, is not a passive environment, and interaction plays an important part in this concept of parasitism. The primary exchanges at the interface are chemical, and Prof. Read proceeded to discuss examples of these obtained from work with which he has been associated in the United States. He concluded by suggesting how host-parasite specificity and pathology might be discussed in terms of chemical exchanges.

The general sessions were devoted to a series of 19 short papers, each being followed by a period of discussion. This type of meeting is useful because it gives an indication of the fields in which the main research is taking place and provides an opportunity for discussion of its progress and the conclusions reached.

The growing interest in marine parasitology was reflected in two papers by Z. Kabata (Marine Laboratory, Aberdeen) and H. H. Williams (University College of Wales, Cardiff). Dr. Williams had examined a number of elasmobranchs caught in British fishing areas and recovered the tetraphyllidean cestodes which they contained. A high degree of host-specificity exists in this group, and, although there are still many unidentified species, a very interesting discussion was given of the physiological, ecological and morphological factors which contribute towards restricting a species to a particular host. Dr. Kabata based his discussion on the parasitological examination of some 500 whiting and haddock and presented some data relating the age of the fish to the parasitic fauna which it supports.

Temperature and climatic conditions have an important influence on the level of helminthic infestation in domestic animals. H. D. Crofton (Bristol) has devised a technique for accurately observing the rate of development of nematode eggs and larvæ from sheep. The data, which he has obtained on the limits of temperature tolerance of different species and the effects of temperature on the rate of development, provided the basis for a useful discussion on the ecology of the parasites in relation to domestic stock. The importance of temperature and moisture-levels on different stages in the life-cycle of *Fasciola hepatica* was discussed by C. B. Ollerenshaw (Central Veterinary Laboratory, Weybridge), with particular reference to the incidence of fascioliasis in Anglesey. Dr. Ollerenshaw was able to correlate the incidence of the disease in this area, which was particularly high during 1958, with meteorological data obtained during the preceding year.

The significance of the trypanosomatid kinetoplast figured in the discussions by three speakers. J. R. Baker (London School of Hygiene and Tropical Medicine) and K. Vickerman (University College, London), in a joint paper, showed a series of electron micrographs of insect and vertebrate trypanosomatids, and the possible functions of the kinetoplast were reviewed with particular reference to kinetoplastic and akinetoplastic strains and to the life-history of the species studied. When trypanosomes (*T. gambiense* and *T. rhodesiense*) are exposed to dilute solutions of acriflavine they become photosensitive and are rapidly killed by light. The kinetoplast of the sensitized trypanosome fluoresces intensely in ultra-violet light, but experiments by P. J. Walker (National Institute for Medical Research, Mill Hill) have indicated that this organelle is not the only site of the photosensitivity.

The role of arthropods as vectors of parasitic infections was discussed in the course of three papers. D. S. Bertram and R. G. Bird (London School of Hygiene and Tropical Medicine) described the subcellular morphology of *Aedes aegypti* with the aid of a series of electromicrographs. This study was particularly concerned with the transmission of Semliki Forest virus, and the presence of virus particles within the cells was correlated with the infectivity of the insects. These workers also suggested that the complexity of the membranes surrounding the anopheline ovary reduces the possibility of the transmission of infection through the mosquito egg. In ticks, however, the membrane structure is simpler, and transovarian transmission of parasitic infections therefore can take place more easily. Transmission in this way of *Babesia divergens* by larvæ of *Ixodes ricinus* following the feeding of adult ticks on infected calves had been observed by Davies and Joyner in the course of a series of transmission experiments carried out at the Central Veterinary Laboratory, Weybridge. The feeding mechanism by which *Ixodes ricinus* obtains infected blood was the subject of an investigation by E. Sutton (King's College, London). Histological preparations were shown to illustrate the digestion of the host tissue which takes place around the inserted mouth-parts. Spectrophotometric measurements of the hæmoglobin content of individual ticks indicate that ticks feed on varying amounts of non-blood and blood tissue.

Parasites in relation to natural fauna were also discussed. A. M. Dunn (Veterinary School, Glasgow) has recorded the intestinal helminth parasites of the three species of wild deer on Rum in the Inner Hebrides. This paper was notable for some very beautiful illustrations of the habitats. The rigour of a littorine habitat was apparent in the discussion by B. L. James (Aberystwyth) of the development and life-history of *Parvatrema homoeotecnum* n.sp., a gymnophalline trematode which parasitizes the gastropod mollusc, *Littorina saxatilis* and oyster catchers. This parasite shows several specialized and primitive features. The perch and pike in Llyn Tejid in Merionethshire are the hosts of a pseudophyllidean cestode, *Triaenophorus nodulosus*. By taking regular nettings, J. C. Chubb (Liverpool) was able to obtain data relating the incidence and development of the parasite to the growth of the fish. Also following this theme of seasonal incidence, but with quite a different parasite, W. N. Beesley (Weybridge) discussed the development and migration of *Hypoderma bovis* and *H. lineatum* in domestic cattle.

Work during recent years has shown that parasitology is a fertile field for the application of new laboratory techniques. Thus, cytochemical techniques were used to characterize the functions of the male accessory and reproductive glands of *Argas persicus* (R. J. Tatchell, Cambridge), and the pseudosuckers and holdfast organ of the trematode *Diplostomum phoxini* (D. L. Lee, Cambridge). The nutritional requirements of the latter have been the subject of *in vitro* cultural studies by C. A. Hopkins and M. O. Williams (Glasgow). In the field of immunology, agar diffusion techniques have been applied to such widely differing subjects as *Eimeria* infections in fowls (M. E. Rose and P. L. Long, Houghton) and schistosomes in monkeys (S. R. Smithers, National Institute for Medical Research). Despite the application of new techniques, parasitology still occasionally requires systematic descriptions, an example of which was the paper by S. T. Fernando (Cambridge) dealing with the developmental stages of *Mecistocirrus digitatus*, a nematode found in the abomasum of cattle in Ceylon, India and the Far East.

The proceedings of this meeting will not be published in detail. The spring meeting in 1962 is to be held in Cambridge during April 3–5.

L. P. Joyner

WATER RESOURCES IN WALES

LARGELY as a result of the water supply difficulties of 1955 and 1957, the Minister of Housing and Local Government (who is also Minister for Welsh Affairs) appointed in February 1958 a committee to advise him on the use and conservation of water resources in Wales. The Committee has already expressed interim views in February 1959 on the Milford Haven barrage scheme (which it favoured), and has recently published its first full *Report on the Water Resources of Wales**.

This report is a notable advance forward in our knowledge of the Water Resources of Great Britain and in their proper employment. The Minister indicated to the Committee that the most urgent problem was to assess the water resources in relation to foreseeable demand, and three guiding questions were posed: (*a*) What are the water resources ? (*b*) What is the exploitable surplus ? and (*c*) How can such surplus best be employed ?

The Committee consisted of persons from different parts of Wales with interests in hydrology but not themselves engineers or technical experts. The report, as a result, considers not only the hydrological survey of Wales carried out by the Ministry's engineers in 1957 but also social, economic and cultural aspects of the problems encountered. The hydrological survey (not generally available) gives detailed estimates of the maximum supply of water which could be obtained from Wales on the assumption that hydrological considerations are the sole governing factor. The Committee, however, examined more than 180 suggested reservoir sites in the light of (*a*) geological structure, (*b*) agricultural interests, (*c*) existing communities, (*d*) amenities, and (*e*) cost. The sites were then placed in one of four categories: '*A*' sites, to which no objection could be seen; '*B*' sites, where a moderate degree of objection was foreseen; '*C*' sites, development of which could only be envisaged if the need for water in the country as a whole were to become over-riding; and lastly, sites rejected as completely unsuitable.

As the Committee also considered the various resources in relationship to conventional impounding reservoirs, regulating reservoirs, estuarine reservoirs and direct abstraction, it will be immediately apparent that there is no clear-cut and definite answer to the first question: "What are the water resources of Wales ?". Appendix 8 of the report, however, sets out the various possibilities: these, on the Committee's definition, range from a minimum of 1,195 million gallons a day to a maximum of 2,895 million gallons a day.

These resources are next considered in relationship to the demand for water. Here the Committee has not only considered the present situation but also has looked ahead into the 'foreseeable future'. This has been taken, despite the hazards of extrapolation, as a period of 30 years. For this purpose Wales is divided into five geographical zones—south-west, north-west, north-east, south-east and central. In only one of these zones, the south-east, has the Committee found serious prospective deficiency of water: in all the others there is not only an adequate amount of available water but also an exploitable surplus. Ample allowance has been made in these calculations for a continued expansion in the Welsh economy and for increased demands for water. The Committee estimates that, taken as a whole, the Principality has an exploitable surplus of resources over demand of between 235 and 800 million gallons a day according to the system of development adopted (this is seen in perspective when it is recollected that public undertakings in England and Wales at present supply some 2,400 million gallons a day).

The Committee suggests that that part of the surplus which can be most easily used to supply areas in England which are short of water is to be found in the upper basins of the Severn, Wye and Dee (the 'central zone'). This is an area of heavy rainfall and very low population with limited local demands on the water resources. The report stresses that this should be achieved by means of regulating reservoirs such as that proposed in the Tryweryn scheme. This type of reservoir regulates the flow of water down the river, and water is then abstracted from the lower reaches: there is no pipe-line as with the impounding reservoir.

---

* Welsh Advisory Water Committee. *Report on the Water Resources of Wales*. Pp. iv+93. (Cmnd. 1231.) (London: H.M.S.O., 1961.) 5*s*. net.

The Committee raises an important point in the suggestion that rural areas where large reservoirs have been sited have not always received adequate economic returns. They believe a case exists for a system whereby material benefit should be received by such areas in addition to the extra revenue available in the form of rate income. Adequate compensation for displaced residents and disrupted farm-economies would also ease the transition from traditional types of land use to water storage. A realistic approach on these lines would help to create a better understanding between the city and town dwellers and the inhabitants of the rural catchment areas.

The report is full of valuable statistical data, and provides for the first time an indication, in the light of economic, social and cultural considerations, of the hydrological situation within the Principality in relationship to present and future needs of water supply. A clear and concise geographical account is also given of each of the five zones demarcated (although the authors of the report have somewhat oddly listed the physical geography as 'geography'; actually the whole of each of the respective chapters falls within the scope of a geographical consideration). As a work of reference and as a guide for future policy decisions the report will be invaluable.

Water in Wales may also raise from time to time 'political' problems regarding the 'export' to England. This aspect is also considered by the Committee. It believes that, in a period when water will become relatively more scarce, Wales will have many advantages for water-seeking firms and for agricultural irrigation. While noting that public opinion in Wales would not take kindly to the idea of a wholesale export of water without reference to long-term needs within Wales, the Committee is able to conclude that Wales has such an abundant rainfall that there is, and will continue to be, a large exploitable and 'exportable' surplus of water if the resources were properly developed by the construction of suitably sited regulating reservoirs. W. G. V. BALCHIN

CHEMICAL COMPOSITION OF PRECIPITABLE WATER VAPOUR OVER THE UNITED STATES

By DRS. HENRY M. PAPÉE and ALBERTO MONTEFINALE

Centre for Aerosol Nucleation, National Research Council of Italy, Via Vettore 4 (Monte Sacro), Rome

DATA on annual average amounts of precipitable water vapour in the atmosphere over several stations of the United States and up to 525 m.b. have recently been published by Reitan[1], and it appeared to be of interest to us to attempt a correlation between these data, Junge's rain-water content analyses[2,3] and the total precipitation values. It was thought, in particular, that further evidence of a connexion between precipitation and such occurrences as may induce changes and activation[4] in aerosols could be obtained in this way. Since about half the stations selected by Reitan for his work coincide with points which were used by Junge, there appeared to be a good possibility of gaining further insight into natural nucleation phenomena.

If the precipitable water vapour π is taken as a potential measure of the water stored in the atmosphere, and other parameters are maintained constant, an increment of precipitation R with increase of π will depend on an effective value of π itself, and therefore on the difference:

$$\alpha\pi - \beta R$$

α and β are constant for the purpose of this article (see later); more generally α is a number which depends on temperature, while β has the dimensions of time.

Therefore:

$$\frac{\mathrm{d}R}{\mathrm{d}\pi} = K(\alpha\pi - \beta R) \tag{1}$$

where K is a constant.

When $\pi = 0$, $R = 0$; equation (1) integrates to:

$$R = \frac{\alpha}{\beta}\left\{\pi - \frac{1}{K\beta}\left[1 - \exp(-K\beta\pi)\right]\right\} \tag{1a}$$

The derivative of (1a) with respect to π can also be written:

$$\frac{\mathrm{d}R}{\mathrm{d}\pi} = \frac{\alpha}{\beta}\left\{1 - \exp(-K\beta\pi)\right\} \tag{1b}$$

Thus, it is significant that for very high precipitable water vapour contents of the atmosphere (1b) approaches α/β, while it is near to zero for very small values of π.

Clearly, the 'tendency of π to precipitate' will depend considerably on temperature. If, however, differences in vertical temperature gradients from station to station are assumed to be such as not to have much influence on the data at hand, it becomes readily possible to correct π for these effects. Rather than make corrections on the basis of the $\pi - T$ empirical relationship and the 'potential temperature' formula, we used an empirical latitude correction. A plot of π against geographical latitude for lower stations (Fig. 1) gives an approximately straight-line relationship, on the basis of which Reitan's data of precipitable water vapour were all reduced to a latitude of 35° N. by means of multiplication by the corresponding values of $(\pi_{35°}) : (\pi_{\text{lat.}})$ which were obtained from the straight line derived by the method of least squares. This procedure results in a plot given in Fig. 2, where the corrected points are seen to fall into a type of pattern which might be expected to be in agreement with equation (1a).

When the exponential in (1*a*) is expanded in series, the expression becomes:

$$R = \alpha\left(\frac{K\pi^2}{2!} - \frac{K^2\beta\pi^3}{3!} + \ldots\right) \tag{2}$$

if *K* is now assumed to depend simply on the quantity of an active chemical species in the atmosphere, and if that quantity were taken, for the purpose of this communication, to be proportional to the concentration *Ch* of the species concerned in the water that dissolves it, multiplied by the volume of precipitation itself:

$$K = aChR$$

substitution into (2) gives:

$$\pi^{-2}(Ch)^{-1} = \alpha\left(\frac{a}{2} - \beta\frac{a^2}{6}(ChR\pi) + \ldots\right) \tag{2a}$$

Similarly, if the ratio Na : Cl (ref. 5) is assumed to influence *K* so that:

$$K = a\frac{\text{Na}}{\text{Cl}}$$

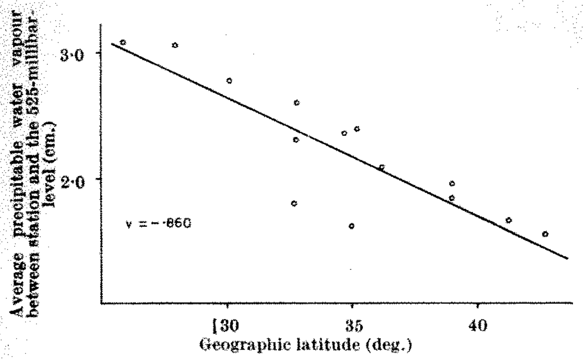

Fig. 1. United States stations; altitude 0–580 ft.

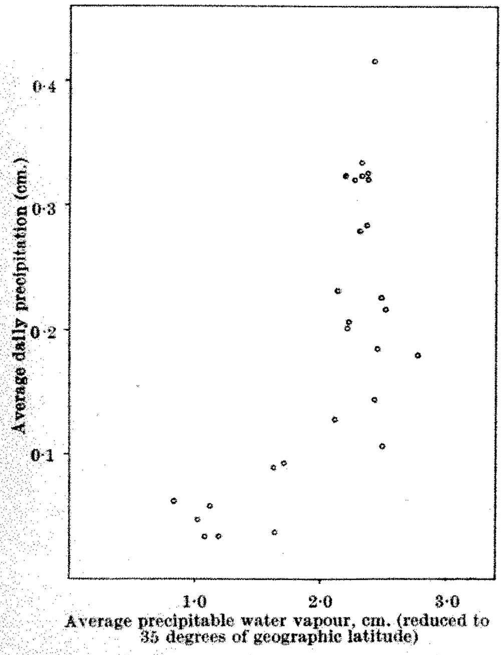

Fig. 2

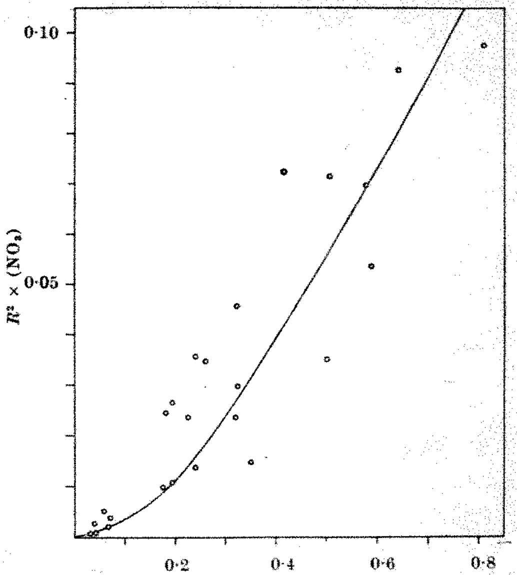

Fig. 3

then equation (2) becomes:

$$\frac{R}{\frac{\text{Na}}{\text{Cl}}\pi^2} = \alpha\left(\frac{a}{2} - \beta\frac{a^2}{6}\frac{\text{Na}}{\text{Cl}}\pi + \ldots\right) \tag{2b}$$

By means of (2*a*), (2*b*) correlation tests: $(\pi^{-2}(Ch)^{-1}) - ChR\pi$ can be carried out; linear correlation coefficients were computed for the following:

$$\text{NO}_3;\ \text{Na};\ \text{K};\ \text{SO}_4;\ \text{Cl};\ \text{NH}_4;\ \text{Ca};\ \frac{\text{Na}^2}{\text{Cl}};\ \frac{(\text{Na}+\text{K})^2}{\text{Cl}};\ \text{Na}\times\text{NO}_3;\ \frac{\text{Na}}{\text{Cl}};\ \frac{\text{Na}+\text{K}}{\text{Cl}}$$

(having expressed *Ch* in gram-equivalents × 10^5 l.$^{-1}$, π and *R* in cm. and cm. × day^{-1} respectively, and using equation (2*b*) for the last two functions listed).

The following values are worthy of note:

Ch	NO_3	$\frac{\text{Na}}{\text{Cl}}$	$\frac{\text{Na}+\text{K}}{\text{Cl}}$	SO_4	NH_4	Ca
r	−0·77	−0·57	−0·60	−0·51	−0·58	−0·46

All others gave $0 > r > -0{\cdot}4$; calculation of the correlation coefficient between $R\pi^{-2}$ and π (equation 1), where the 'salt effect' was neglected, yields $r = 0{\cdot}21$.

As can be seen, NO_3 is the chemical species that fits equation (2*a*) most closely. Equation (1*a*) can be written in this case, after substitution:

$$R^2\text{NO}_3 = \frac{\alpha}{\beta}\left\{\pi' - \frac{1}{a\beta}\left(1 - \exp(-a\beta\pi')\right)\right\} \tag{3}$$

where

$$\pi' = \text{NO}_3R\pi$$

$a\beta$ can be obtained in first approximation from the linear regression parameters of a plot of $\pi^{-2}\text{NO}_3^{-1}$ versus $\text{NO}_3R\pi$ (equation 2*a*) since its value is:

$$\frac{3\ \text{gradient}}{\text{intercept}} = 3{\cdot}6 \pm 0{\cdot}5$$

Using this value, α/β can be computed with good approximation from equation (3); we find:

$$\frac{\alpha}{\bar{\beta}} = 0{\cdot}209 \pm 0{\cdot}015$$

This now enables a check of $\alpha\beta$ to be carried out; the method of consecutive adjustments, using the *S.D.* of equation (3) as a monitor, yields a value of $\alpha\beta$ in agreement with that obtained previously.

Fig. 3 illustrates a plot according to equation (3) and the calculated line. The standard deviation of this function is found to be:

$$S.D._{R^2NO_3} = 0{\cdot}013$$

whereas, introducing the constants computed into equation (1) we calculate the value of:

$$S.D._R = 0{\cdot}10$$

We are now in the process of extending the computations based on the use of nitrate to the four seasons during 1955–60. While the results obtained will be the subject of a future publication, it can now be stated that the same correlation appears to exist throughout, and that consistency appears to be higher during the warmer seasons than in the cold ones.

We are indebted to Prof. V. Caglioti for his help and encouragement, and to Prof. G. Fea for the interest he has shown in our work.

CRYSTALLIZATION IN WOOL KERATIN

By Dr. ALLAN SKERTCHLY

Textile Physics Research Laboratory, Department of Textile Industries, University of Leeds

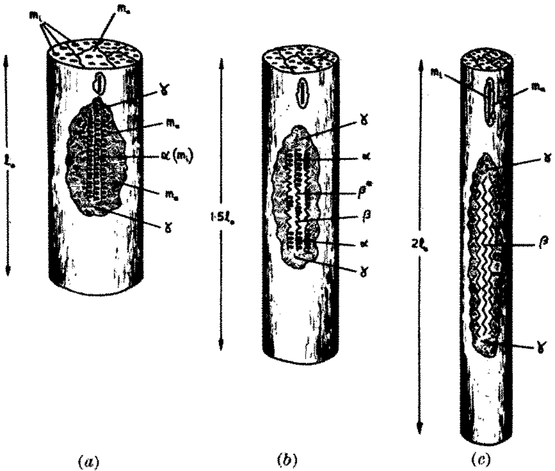
WITH the advent of rapid scanning X-ray diffractometry[1,2] it has become possible to investigate, more fully, certain aspects of crystallization in the fibrous proteins. In particular, it is now apparent that crystallization in wool keratin may be a fruitful field of study. One of the simplest systems to investigate is that of the keratin–water complex, both under external stress free, and tensile stress deformation, conditions. The degree of hydration of the keratin component is intimately related to the type of crystallization observed, and some aspects of this relationship are described here.

Present-day hypotheses[3,4] tend to support the view that unstrained wool keratin consists of 'crystalline' microfibrils embedded in an 'amorphous', or at least somewhat disordered, 'matrix'. Evidence from electron microscopy[5] suggests that the microfibril/matrix areal ratio is near unity, and data from infrared spectroscopy[6] are compatible with the idea that the most readily deuterium exchangeable fraction is an 'amorphous' region, and most probably the matrix.

The lateral dimensions of the microfibrils are approximately the minimum required[7] in order to secure a 'crystalline' X-ray reflexion. For this reason, and because the matrix is 'disordered', it is reasonable to ascribe the origin of the wide-angle X-ray diffraction pattern to interference from within the microfibrils. Before proceeding, it is necessary to distinguish between the configuration of a crystallographic component of structure and the configuration of the fibre as a whole. Thus, in the present case, the maximum amount of material available for the crystalline phase is 50 per cent, and it is normally assumed that an appreciable fraction of the molecules in the microfibrils are in the helical configuration which gives rise to the characteristic reflexions. However, we may also say, loosely, that the fibres are in the α-form, by which we simply mean that chains in the α-configuration are dominant in the crystalline regions.

Fig. 1*a* shows in outline the gross details of the generally accepted model of structure for wool keratin fibres in the 'dry' state. If the system is hydrated, for example, soaked in water at room temperature (18° C.) for a reasonable period, it is observed: (1) that the equatorial spacing about 9·8 Å. is little altered[8,9]; (2) (from the results of this investigation) that there is little change (less than 5 per cent) in the radially 'integrated' scattered intensity of the 9·8 Å. reflexion. These results and those of the deuterium exchange reaction[6] suggest that few water or deuterium oxide molecules penetrate into the helical interstices. Thus, under conditions of zero external stress the crystallographic configuration of both dry and hydrated keratin remains unaltered, at least to within the limitations of detectability of the present detecting system.

With the application of an external stress of sufficient magnitude to cause an appreciable strain, an entirely new and more complicated system is developed. The nature of the end-products of the reaction depend, in an as yet ill-defined manner, on



(*a*) (*b*) (*c*)

m_i, microfibrils; m_a, matrix; l_o, original length

Fig. 1. (*a*) Model of unstretched wool keratin. Microfibrils, α-transformable helices; γ, invariant fraction. Matrix, an initially disordered region of high water accessibility. (*b*) Wool stretched 50 per cent and dried. β-crystalline phase derived from α. β*, a mixed α- and β-crystallite. Matrix, becoming strained and more ordered. (*c*) Wool stretched 100 per cent and dried. β-Crystalline phase derived from all the formerly ordered α-material. Matrix, attaining a further degree of order

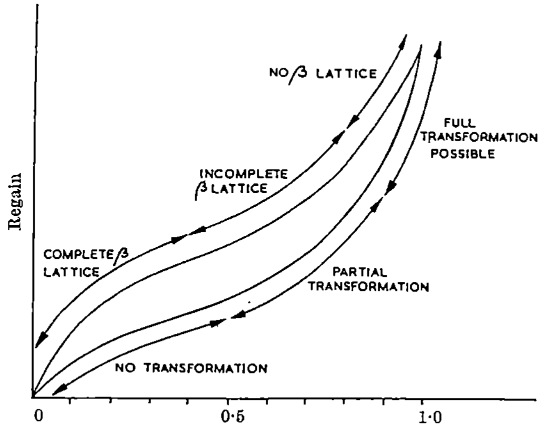


Fig. 2. The relationship of partial vapour pressure to the extent of crystallization in the β-form for wool keratin stretched up to 50 per cent. The absorption curve represents the extent of transformation of α-helices into β-crystallites, for stretching at the vapour pressures shown, after the fibres have been dried in the extended condition at 105° C. The desorption curve shows the extent of β-crystallization during lowering of the vapour pressure, after the fibres have been stretched wet to 50 per cent extension

the initial vapour pressure under which the fibres are stretched, and on the external conditions into which the fibres are finally brought.

In this connexion it is of value to consider the reaction products which may be obtained under two important limiting sets of conditions: (1) when a stress is applied to the fibres under a number of different partial water vapour pressures, and the then extended fibres are dried at 105° C. (conditions where there is a maximum likelihood of β-crystallites being formed); (2) when fibres are stretched wet and then the extent of formation of β-crystallites for progressively reduced vapour pressures is observed. In all cases the fibres were extended, either up to the maximum possible (determined by their initial conditions), or to an arbitrary and convenient limit of 50 per cent. The extent of crystallization was determined by a technique, depending on the magnitude of the radially integrated reflexion intensities, which has been reported elsewhere[10].

The results of one such set of crystallization experiments are summarized in Fig. 2. It will be seen that there is a strong correlation between the increase in the initial moisture content (regain) and the predisposition of the system to form β-crystallites after stretching and drying. Thus, it seems likely that an intermediate hydrate is a necessary precursor to an observable crystalline β-phase. The upper curve of Fig. 2, the desorption curve, confirms this view, for it is found that crystallization does not in fact occur until after the relative water vapour pressure falls below a certain value (0·8), and thereafter continues to increase until a limiting value, which represents the optimum equilibrium concentration of material in the ordered crystalline β-form, is attained.

In these experiments it was not found possible to obtain any evidence for the existence of crystalline β-keratin unless the vapour pressure of the extended material was reduced below that at which the extension took place. This result is in conflict with the interpretation of some observations reported earlier by Bendit[11].

The crystallization at 50 per cent extension of the mixed system of α- and β-keratin affords a striking illustration of the effectiveness of the rapid scanning technique, and some sequences from the X-ray diffractometer records are, therefore, reproduced in Fig. 3. These show the reappearance of the crystalline α- and β-reflexions as the solvent vapour pressure is reduced and indicate clearly the nature of the phenomenon taking place.

In earlier work[12] it has been established that at intermediate extensions the dehydrated equilibrium crystalline configuration contains a mixed crystallite which does not contribute to either the α- or the β-crystalline X-ray diffraction pattern. This has been designated β* (ref. 13). However, the evidence available now suggests that hydrated and extended material may consist of unchanged α-chains, hydrated α-chains, hydrated β*-material, and hydrated β-material. Further, it is observed[14] that the limiting reversible extension of the system is near 100 per cent. However, unconstrained α-helices would be expected to extend by at least 120 per cent[14], and measurements on the meridional reflexions confirm this[15]. Any interpretation of the changes in the equilibrium relative intensities of the α- and β-crystalline reflexions indicates that a smooth and continuous transition from the crystalline α- to β-phase occurs. These facts, taken together, suggest that there is an inextensible component of the microfibril in series with the helical α-crystalline phase. The work of Middlebrook[16] has suggested that cystine-rich regions alternate with cystine-poor regions along the fibre

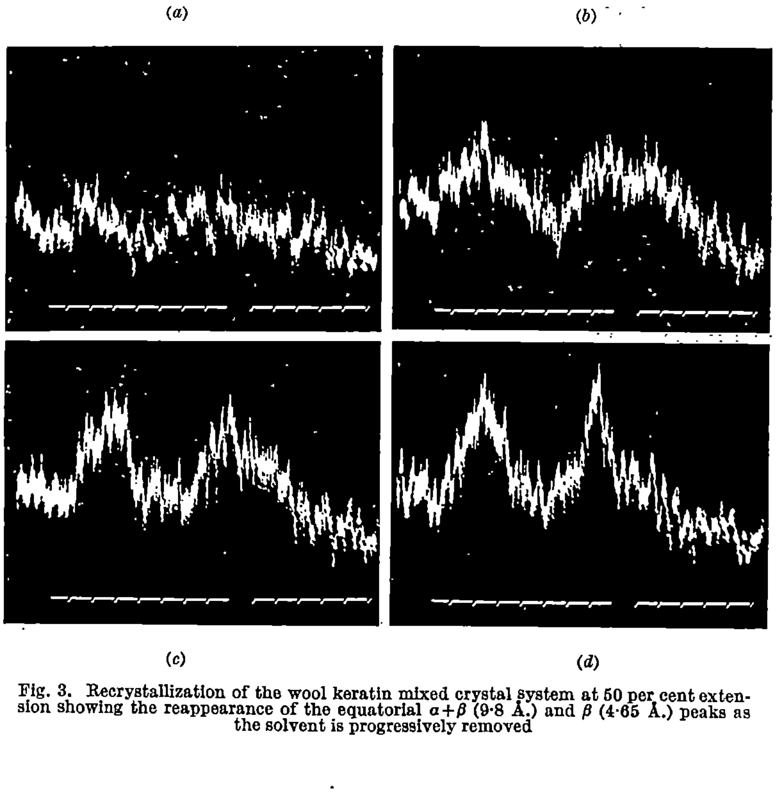

Fig. 3. Recrystallization of the wool keratin mixed crystal system at 50 per cent extension showing the reappearance of the equatorial α+β (9·8 Å.) and β (4·65 Å.) peaks as the solvent is progressively removed

axis and a component of higher sulphur content, γ-keratose[17], has been isolated. Thus, it is proposed to label the inextensible phase γ-keratose. Since this phase is not sufficiently well ordered to contribute to the discrete X-ray reflexions and is likely to be closely linked, it is suggested that hydration will have little effect on it. Because of this, it will be taken to form a largely unalterable component of the microfibrils. This analysis also leads to the value of 40 per cent for the 'crystallinity' of the fibre as a whole, a figure which compares well with those obtained by other workers and in particular 44 per cent by Hailwood and Horrobin[18].

Earlier interpretations[15] also suggest that it is only at extensions near 100 per cent that all the α-crystalline phase is transformed into the β-crystalline phase.

Thus the two extensions of 0 and 100 per cent form limiting cases for relatively simple keratin–water complexes. At any intermediate extension the possibility of several more components being present suggests itself. Table 1, therefore, indicates in outline the sequence of phases that may be involved in the α–β transformation, and underlines, too, the complexity of the situation in what was once thought[19] to be a simple polymorphic transformation. Next it is desirable to return to Fig. 1 and to contemplate the nature of the interaction between the matrix and the microfibrils.

Table 1. SEQUENCE OF PHASES INVOLVED IN THE α–β TRANSFORMATION IN WOOL KERATIN

Condition of fibres	Phase states		Phase designation
	Microfibrils	Matrix	
Dry under no external stress	$\alpha + \gamma$	Dehydrated	α
Wet under no external stress	$\alpha + \gamma$	Hydrated	α_H
Wet under stress extended 50 per cent	$\alpha + \alpha_H + \beta^*_H + \beta_H + \gamma$	Hydrated	Mixed M_H hydrate
Dry under stress extended 50 per cent	$\alpha + \beta^* + \beta + \gamma$	Dehydrated	Mixed dehydrate M
Wet under stress extended 100 per cent	$\beta_H + \gamma$	Hydrated	β_H
Dry under stress extended 100 per cent	$\beta + \gamma$	Dehydrated	β

Since the transformation from crystalline α to crystalline β material is uniform, there is no evidence to suggest that marked gross crystallographic differences exist along the transformable microfibrillar component. On the other hand, evidence from the analysis of the stress-strain curves[14,19] leads us to expect three distinct phases which may affect the extensometric characteristics. Successively, the fibre becomes more difficult to transform, but since initially Young's modulus of the matrix may be supposed to be small[3], the hindering of the transformation by the matrix is also initially small.

It is, however, reasonable to suppose that on extension the initially disordered matrix becomes more ordered and also contributes increasingly to the resistance to deformation, while the stress contribution of the crystalline material follows a uniform course depending on the difference in energy between the α- and β-forms.

The recent work of Crewther and Dowling[20] has reaffirmed that there exists a high degree of interaction between the microfibrils and the matrix under suitable conditions, but there does not seem to be any direct evidence to suggest, as has Feughelman[21], that the microfibrils themselves have a periodic sequence of X (more easily extensible) and Y (less easily extensible) zones. All that can be definitely asserted, in the absence of the crystallographic transformation data, is that the system (microfibril–matrix), acting as a whole, produces the observed supercontraction and stress-strain discontinuities. The view to be taken here, however, is that as the crystallographic transformation in the microfibrils is reasonably uniform throughout the entire range of extensions, it is the matrix, with differing degrees of deformability, that is the source of complexities in the other observable physical parameters. The contribution of the microfibrils to the developed stress over the whole transformation-range may thus be derived from an extrapolation of the wet stress at low extensions, assuming the simple uniform transformation of the crystallites. On the basis of this assumption, it is possible to calculate a value for the difference in free energy between the α-phase and the β_H-phase using the relationship $\Delta F^0 = \lambda\frac{ARf}{k}$ (ref. 14). This equation holds for the condition $[\alpha] = [\beta]$, which is obtained near 50 per cent extension.

If we assume a single NH . . . O = C hydrogen bond in a Pauling and Corey type α-helix[22] to be the fundamental flow unit, we find, for hexagonal packing, the following values for certain of the required parameters:

A, the cross-sectional area $\simeq (5{\cdot}8)^2 \times 3{\cdot}46 \times 3{\cdot}7^{-1} \times 10^{-16}$ cm.^{2}; λ, the translation distance of a single segment of chain, $\simeq 6{\cdot}35 \times 10^{-8}$ cm.; $R = 1{\cdot}99$ calories/mole deg.; $k = 1{\cdot}375 \times 10^{-16}$ erg/deg.

The remaining parameter, f, the equilibrium stress, is rather difficult to establish accurately, owing to long-term stress relaxation. However, it might reasonably be argued that in so far as the reversible crystallographic transformation is concerned, equilibrium is, in fact, reached in a relatively short time (within the duration of the experiment). Stress relaxation continuing after this time may be due to a significant change in keratin structure not within the purview of present considerations. Such possibilities have been confirmed recently by Woods[14] and Kubu *et al.*, who have shown that the first (rapid) stage of relaxation involves hydrogen bonds only, while long-term relaxation depends to a large extent on primary (particularly disulphide) bond fission. If Crewther and Dowling's ideas[20] are substantiated, the matrix is, in fact, rich in sulphur in comparison with the transforming section of the microfibrils. Their suggestions thus provide confirmatory evidence for the keratin model outlined above. As an approximation, the extrapolated value of stress adopted by Peters and Woods[14] from Woods's earlier data may be chosen. This yields an extrapolated stress of $\simeq 8 \times 10^8$ dynes/cm.^{2} at $\simeq$ 50 per cent extension in water at about 30° C. Since the microfibrils are in effect taking all the stress at low extensions, the effective loading is approximately twice this value, namely, 16×10^8 dynes/cm.^{2}.

This leads to a free-energy difference of $\simeq 4{\cdot}5$ kcal./mole, which may be compared with a figure derived by Ruoff *et al.*[23] of 4·7 kcal./mole, and thus further confirms the adequacy of the molecular model involved.

Further work on elucidating the transformation mechanism, and the factors involved in crystallization in wool keratin is proceeding.

I am grateful for the assistance of Prof. J. B. Speakman, H. J. Woods and the Wool Textile Research Council.

PEAK-SHIFT TECHNIQUE IN GAS-LIQUID CHROMATOGRAPHY: TRIMETHYLSILYL ETHER DERIVATIVES OF ALCOHOLS

By STANLEY H. LANGER* and PETER PANTAGES

U.S. Bureau of Mines, Pittsburgh 13, Pa.

STABLE solid crystalline derivatives with melting points in the range of 50°–300° C. have been of greatest interest for classical qualitative organic chemical analysis and identification. Recently, the growth of the analytical application of mass spectrometry[1,2] and particularly gas chromatography[3–11] has stimulated considerably greater interest in liquid derivatives of organic compounds with their increased volatility, reduced adsorption on solid surfaces and enhanced separation factors. Despite this, with the exception of several peak subtraction techniques and the hydrogenation of unsaturated materials[12], identification and analysis via the 'peak shift' resulting from conversion of volatile materials to volatile derivatives has received only limited attention. Some advantages, as well as complications, can be illustrated by consideration of a hydrogenated Fischer–Tropsch fraction, b.p. 110°–115° C., after hydrogenation obtained from a synthesis using iron nitride catalyst[13].

The principal components of the Fischer–Tropsch fraction were octane, 2-methyloctane, nonane, 1-butanol, 2-methylbutanol, and 1-pentanol. Treatment of the mixture with hexamethyldisilazane was used to convert the alcohols to their trimethylsilyl derivative[3]. Some retention volume data for three liquid phases are shown in Table 1. The trimethylsilyl ethers will emerge from the column before the parent alcohols on the polar polyesteramide 'Flexol 8*N*8' liquid phase (because of hydrogen bonding, the alcohols tend to be retained) and after the parent alcohols on Dow Corning 'Silicone 550' (solubility increased as solubility parameters are more nearly equal[14]). Thus, peak shift should be a definite aid to identification after treatment with a selective reagent such as hexamethyldisilazane. Furthermore, the volatile derivative provides access to another gas chromatographic parameter for identification similar to that obtained from chromatography of one compound on two liquid phases[15,16]. That is, a plot of log retention volume of parent compound versus log retention volume of derivative is linear for a homologous series. A plot of such values for Dow Corning 'Silicone 550' is shown in Fig. 1. The 2-methyl and normal alcohols apparently fall on different lines. The linearity of plots such as that shown in Fig. 1 is to be expected when the logarithm of retention volumes of both the parent compounds and derivatives are linear functions of the number of carbon atoms in the chain.

Difficulties are encountered when members of different classes occur in the same mixture[16] except when there is a large disparity in amounts present. Thus, the retention volume of 1-butyl trimethylsilyl ether coincides with that of octane on silicone oil and on 'Flexol 8*N*8', while the trimethylsilyl derivative of pentanol tends to emerge close to nonane. However, the disappearance of the alcohol peak is definite and the increase in the hydrocarbon peak, if there is a hydrocarbon present, is often apparent. The parent compound of interest may also be trapped and reacted with hexamethyldisilazane for definite identification. Other workers[10] at the U.S. Bureau of Mines have performed identifications similar to this by comparing retention volumes of sulphur-

●, *n*-alcohols; ○, 2-methyl alcohols

containing materials and derived hydrocarbons after desulphurization.

Chromatograms illustrating the behaviour of the Fischer–Tropsch fraction on pentatriacontane before and after treatment with hexamethyldisilazane are shown in Fig. 2. From curve B, it is seen that the alcohols are not resolved and are eluted early (9–16 min.) from the non-polar hydrocarbon liquid phase so that the hydrocarbon portion of the chromatogram is simplified. The shifting of the alcohols after treatment with hexamethyldisilazane, as shown in curve *A*, is in itself diagnostic; in addition to identification, analysis of the alcohols as well as hydrocarbons is now possible on the non-polar liquid phase by calibration against one of the hydrocarbons or addition of an 'internal standard' which may be a hydrocarbon or a hydroxyl-containing material. The peak at 6–9 min. is due to excess hexamethyldisilazane and some hexamethyldisiloxane due to reaction with water[6]. The reaction with, and removal of, water by hexamethyldisilazane to form hexamethyldisiloxane is an additional advantage of this reagent. Peaks at about 21, 41, and 45 min. are due to octane, 2-methyloctane and nonane. Identity of the alcohols is indicated in Fig. 2.

Experience with the trimethylsilyl ethers as derivatives for alcohols indicates that additional development of convenient reagents for functional groups which react quantitatively to give volatile

Fig. 2. derivatives should increase the utility of gas chromatography for organic analysis appreciably. It is desirable also that such reagents be specific and that the retention volumes of derivatives obtained be considerably different from those of present compounds.

MANNOSYL D-GLUCOSAMINE HYDROCHLORIDE ISOMERS

N-Mannosyl D-Glucosamine Hydrochloride

When a D-glucosamine hydrochloride-D-mannose mixture (each 5 per cent w/v in water) was applied to Whatman No. 3 paper, heated for 15 min. at 100° and thereafter submitted to ionophoresis in 0·2 *M* acetate buffer *p*H 5 at 8 V./cm. for 4 hr. a new component, now identified as *N*-mannosyl D-glucosamine hydrochloride, was detected. This novel compound ($M_{\text{glucosamine}}$ 0·56) gave positive reactions with ninhydrin[1], the Elson–Morgan reagents[2], aniline hydrogen phthalate[3], alkaline silver nitrate[4] and alkaline triphenyltetrazolium chloride[4], but not with naphthoresorcinol[2]. In order to isolate larger quantities of *N*-mannosyl D-glucosamine hydrochloride it was necessary to carry out the reaction described above using the sugar mixture (50 gm.) freeze-dried on to cellulose powder (200 gm.). Batches of the products (4–6 gm.) were then eluted with water, freeze-dried, dissolved in 0·3 *N* hydrochloric acid and applied to a column of 'Zeokarb 225' [H^+] (length, 53 cm.; diam., 8 cm.). Elution with 0·3 *N* hydrochloric acid and analysis of the 50 ml. fractions collected showed separations between D-mannose (tubes 20–30; optically active), 5-hydroxymethyl 2-furaldehyde[5] (tubes 86–96 ; absorption at 284 mμ), *N*-mannosyl D-glucosamine hydrochloride (tubes 96–106; determined by Elson–Morgan[6] and ninhydrin[7] reagents) and unreacted D-glucosamine (tubes 140–175; optically active, Elson–Morgan and ninhydrin-positive). The 5-hydroxymethyl 2-furaldehyde was characterized by its ultra-violet absorption spectrum ($\lambda_{\max.}$ 284 mμ), chromatographic behaviour, partition coefficients between two different solvent systems (0·3 *N* hydrochloric acid–chloroform and 0·3 *N* hydrochloric acid–ether) and isolation of its 2 : 4-dinitrophenylhydrazone (m.p. and mixed m.p. 200–1°). The solution containing *N*-mannosyl D-glucosamine was neutralized by extraction with a chloroform solution of di-*n*-octylmethylamine[8] and freeze-dried (yield 50–100 mgm.).

N-mannosyl D-glucosamine hydrochloride showed no ultra-violet absorption and was virtually unchanged in 0·3 *N* hydrochloric acid at room temperature during two weeks. Complete hydrolysis of *N*-mannosyl D-glucosamine hydrochloride (300 mgm.) occurred when it was heated in water (30 ml.) at 100° for 12 hr. and was accompanied by extensive browning. The products were separated on the ion-exchange column and characterized as D-mannose, 40 mgm. (isolated as its *p*-nitroanilide m.p. and mixed m.p. 208°), a neutral sugar present in much smaller amount (separated from mannose by paper chromatography; probably glucose from its R_F value and the ionophoretic mobility of its borate complex), 5-hydroxymethyl 2-furaldehyde (isolated as its 2 : 4-dinitrophenylhydrazone m.p. 201°) and D-glucosamine hydrochloride (88 mgm. obtained crystalline with $[\alpha]_D + 86°$ (init.) → + 69° (equil.) (*c*, 1·69 in water) and further characterized as its *N*-carbobenzoxy derivative, m.p. and mixed m.p. 211°–213° (*d*)). When *N*-mannosyl D-glucosamine hydrochloride was left in sterile water at room temperature it was almost completely hydrolysed in 30 days to glucosamine hydrochloride and mannose. No ultra-violet absorption attributable to 5-hydroxymethyl 2-furaldehyde was detectable. Direct determination of the mannose (assayed with orcinol–sulphuric acid[9]; chromogen identical with that of authentic mannose) and glucosamine hydrochloride (Elson–Morgan reagents[6]; chromogen $\lambda_{\max.}$ 530 mμ) content of *N*-mannosyl D-glucosamine hydrochloride revealed a ratio by weight of glucosamine hydrochloride to mannose of 98 : 95, confirming that it contained equimolar proportions of the two sugars. The instability of the new compound in aqueous solution precludes the possibility of an *O*-glycosyl linkage. When the condensation was effected between ^{14}C-mannose and glucosamine hydrochloride it was found that the 5-hydroxymethyl 2-furaldehyde obtained both from the reaction mixture and the degradation of the *N*-mannosyl-D-glucosamine was radioactive as indeed was the *N*-mannosyl D-glucosamine hydrochloride. Hence the 5-hydroxymethyl 2-furaldehyde originates from the mannose moiety as would be expected for a glycosylamine. *N*-mannosyl D-glucosamine hydrochloride gave negative results in the methylene blue, 2 : 6-dichlorophenol–indophenol and Seliwanoff tests for Amadori compounds[10,11], and its infra-red spectrum did not contain a peak at 1,720 cm.$^{-1}$ due to a carbonyl group such as has been observed in the infra-red spectra of certain Amadori compounds[12].

Indirect evidence in support of the glycosylamine structure accrues from a study of the formation of compounds analogous to *N*-mannosyl D-glucosamine hydrochloride by heating several other mixtures of amino-sugars with reducing sugars and their derivatives. Since no analogous compound was produced from *N*-acetylglucosamine and a reducing sugar or from glucosamine hydrochloride and non-reducing sugars (mannitol, α-methylmannoside, 1-deoxy D-glucose, sorbitol, dulcitol and α-methylglucoside) it appeared that such reactions were a consequence of reaction between the reducing group of a sugar (aldose, not a ketose) and the amino group of a second compound. Thus mannose formed a condensation compound not only with D-glucosamine and D-galactosamine hydrochlorides but also with the hydrochlorides of D-glucosaminol and 2-aminoglycerol. Another necessary condition appears to be that the C_2 position of the reducing sugar should not be substituted. Thus while condensation compounds were formed from 3-*O*-methyl and 3 : 4-di-*O*-methyl D-glucose and 3 : 4-di-*O*-methyl D-mannose when heated with D-glucosamine hydrochloride, no such compounds were detected with 2 : 3-di-, 2 : 3 : 6-tri- and 2 : 3 : 4 : 6-tetra-*O*-methyl D-glucose. Steric hindrance is the most likely cause of this phenomenon.

6-O-Mannosyl D-Glucosamine Hydrochloride

Since the work reported in the previous article, we have found that under more vigorous conditions (3 hr. at 120°) disaccharides of the *O*-glycosyl type are also formed. The isolation and characterization of one of these, 6-*O*-mannosyl D-glucosamine hydrochloride, is the subject of the present communication.

After heat treatment, the resultant products were extracted with water and boiled for 12 hr. to hydrolyse the *N*-mannosyl D-glucosamine hydrochloride present since this had a similar elution position to the oxygen-linked disaccharides on 'Zeokarb 225' (H^+, 200–400 mesh, 4½ per cent cross-linking). Subsequent fractionation on the resin yielded the residual disaccharides in two major fractions *A* (250 mgm.) and *B* (100 mgm.), being the products from 10 gm. of reaction mixture. *B* was homogeneous ($R_{\text{glucosamine}}$ 0·35) on a paper chromatogram irrigated with the organic phase of butan-1-ol, ethanol and water (4 : 1 : 5) while *A* contained two components ($R_{\text{glucosamine}}$ 0·35 and 0·47). *B* reacted with ninhydrin[1], the Elson–Morgan reagents[2], alkaline silver nitrate[4], aniline hydrogen phthalate[3], alkaline triphenyltetrazolium chloride[4], but not naphthoresorcinol[2]. It had $[\alpha]_D^{20} + 55°$ (*c*, 1·0 in water) and a mobility 0·7 that of glucosamine when separated by paper electrophoresis in 0·2 *M* acetate buffer *p*H 5.

Complete hydrolysis of *B* with 2 *N* hydrochloric acid for 3 hr. at 100° yielded equimolar amounts of mannose and glucosamine hydrochloride. These results suggested that *B* was an *O*-mannosyl glucosamine hydrochloride. *N*-acetylation[13] of *B* (250 mgm.) yielded a product (250 mgm.; $R_{\text{glucosamine}}$ 0·6) the chromogen of which exhibited 26 per cent of the absorption at 590 mμ of an equal weight of *N*-acetylglucosamine in the Morgan–Elson determination[14]. Reduction of *N*-acetyl *B* (200 mgm.) with sodium borohydride (200 mgm.) in water (20 ml.) at room temperature for 5 hr. yielded a crystalline *O*-mannosyl 2-acetamido 2-deoxy glucitol (43 mgm.; from methanol–acetone), m.p. 202°–203°; $[\alpha]_D$ − 50·6° (*c*, 1·0 in water). Found: C, 43·5; H, 6·9; N, 3·6. Calc. for $C_{14}H_{27}O_{11}N$: C, 43·6; H, 7·1; N, 3·6 per cent. Hydrolysis with 2 *N* hydrochloric acid for 3 hr. at 100° gave D-mannose and D-glucosaminol, establishing that the glucosamine-moiety formed the reducing portion of the original disaccharide. On periodate oxidation, the *O*-mannosyl 2-acetamido 2-deoxy glucitol consumed 3·9 moles of periodate and liberated 1·8 moles of formic acid per mole of alcohol. No formaldehyde was liberated. Reduction of the periodate oxidized disaccharide alcohol followed by hydrolysis with 0·5 *N* hydrochloric acid at 100° for 1 hr. yielded *inter alia* 2-amino 2-deoxy glyceritol. Hence the disaccharide alcohol was 6-*O*-D-mannopyranosyl 2-acetamido 2-deoxy D-glucitol. Application of Hudson's rules in the manner used by Stavely and Fried[15] to assess the configuration of the mannosyl residue in mannosido–streptomycin gives a value (*A*) of *c*. − 18,000 for the contribution of carbon atom one of the mannose residue to the molecular rotation. The negative value of *A* (cf. A_{OMe} = 14,230) indicates a β-linkage in the disaccharide alcohol. The rotation of the 6-*O*-mannosyl glucosamine hydrochloride, that is, + 55°, compares favourably with the rotations of related 6-*O*-β-D-mannosyl disaccharide derivatives[16].

The disaccharide probably arises from a condensation between 1 : 6-anhydro-D-mannopyranose, formed during the pyrolysis, and D-glucosamine hydrochloride. Indeed, a component with the same R_F value as the β-anhydro sugar has been detected in the pyrolysis mixture, which is not unexpected since pyrolysis is used in the preparation of the anhydro sugar from ivory nut mannan[17]. It is noteworthy that a heated mixture (1 : 1) of this anhydro sugar and D-glucosamine hydrochloride gave a 20 per cent greater yield (by weight and by Elson–Morgan reaction[6]) of *O*-mannosyl glucosamine type disaccharides than a heated D-mannose D-glucosamine hydrochloride mixture. Furthermore, L-rhamnose (6-deoxy-L-mannose), which cannot form a 1,6-anhydro derivative, did not yield Elson–Morgan-positive[6] disaccharides.

We are indebted to Dr. N. K. Richtmyer for a sample of 1 : 6-anhydro β-D-mannopyranose and one of us (D. B. E. S.) thanks the University of Birmingham for a scholarship.

COUPLING OF PHOSPHORYLATION TO ELECTRON AND HYDROGEN TRANSFER BY A CHEMI-OSMOTIC TYPE OF MECHANISM

By Dr. PETER MITCHELL

Chemical Biology Unit, Zoology Department, University of Edinburgh

At present, the orthodox view of the coupling of phosphorylation to electron and hydrogen transfer in oxidative and photosynthetic phosphorylation stems from knowledge of substrate-level phosphorylation[1,2]. It is based, consequently, on the idea that water is expelled spontaneously between two chemical groups, *A* and *B*, by the formation of a strong bond (of low hydrolysis energy), and that subsequent or simultaneous oxidation or reduction of *A–B* to *A–B** can result in a weakening of the bond, popularly written $A \sim B^*$, so that adenosine triphosphate (ATP) can be synthesized by coupling the opening of $A \sim B^*$ to the closing of the 'high-energy bond' between adenosine diphosphate (ADP) and phosphorus through group transfer systems of appropriate substrate and oxido-reduction-carrier specificities[3–5]. There are a number of facts about the systems catalysing oxidative and photosynthetic phosphorylation that are generally acknowledged to be difficult to reconcile with this orthodox (chemical) view of the mechanism of coupling. For example: (*a*) The hypothetical 'high-energy' intermediates (for example, reduced diphosphopyridine nucleotide (DPNH) ∼ ?, reduced flavin adenine dinucleotide (FADH) ~ ?, cytochrome ~ ?) are elusive to identification[4,6]. (*b*) It is not clear why phosphorylation should be so closely associated with membranous structures[7–9]. It has sometimes been assumed that digitonin-treated mitochondrial 'particles' can couple oxidation to phosphorylation without membranes[10]; but it is doubtful whether this assumption can be justified, for such 'particles' give only poor respiratory control and contain much lipid[11], which may well exist as a leaky membrane[12]. (*c*) Coupling may vary with the stress, causing variation of respiratory control without corresponding variation in phosphorus/oxygen quotient[4,13]—a phenomenon difficult to explain in terms of molecular stoichiometry. (*d*) Hydrolysis of external ATP by mitochondria causes reduction of internal DPN, accentuated by the oxidation of succinate[14]. There is disagreement as to what complex assumptions offer the better explanation[15]. (*e*) Uncoupling can be caused at all three hypothetical oxido-reduction sites in mitochondria by agents that do not share an identifiable specific chemical characteristic[4] (for example, dinitrophenol, dicoumarol, salicylate, azide). (*f*) Unexplained swelling and shrinkage phenomena accompany the activity of the phosphorylation systems[7,9a,11,16].

Structural features have been invoked as the causes of the departure of the phosphorylation systems from 'ideal' behaviour[4,14,17]; but, as Green has pointed out in a far-sighted paper[18], although the structural features have been recognized as playing an important part in the catalytic activity of multi-enzyme systems, they have so far been treated rather conservatively. The structural (or supramolecular) features have, in fact, generally been regarded only as modifiers of the basic chemical type of coupling process outlined above. The general conception of enzyme-catalysed group translocation that we have been developing in my laboratory for some years[19] offers a more radical approach to the problem; but this has not, so far, been made use of by those working in the field of oxidative and photosynthetic phosphorylation.

The purpose of this article is to suggest that in view of the difficulties confronting the orthodox chemical conception of coupling in oxidative and photosynthetic phosphorylation, one might now profitably consider the basic requirements and potentialities of a type of mechanism that is based directly on the group translocation conception. This type of mechanism differs fundamentally from the orthodox one in that it depends absolutely on a supramolecular organization of the enzyme systems concerned. Such supramolecularly organized systems can exhibit what I have called chemi-osmotic coupling[19c,20], because the driving force on a given chemical reaction can be due to the spatially directed channelling of the diffusion of a chemical component or group along a pathway specified in space by the physical organization of the system[20]. We shall consider chemi-osmotic coupling between the so-called ATPases on one hand and the electron and hydrogen transfer chain on the other: mediated by the translocation of electrons and the elements of water across the membrane of mitochondria, chloroplast grana, and chromatophores.

The first basic feature of the chemiosmotic coupling conception is a membrane-located reversible 'ATPase' system[20b] shown very diagrammatically in Fig. 1. This system, which may include lipids and other components as well as proteins, is assumed to be anisotropic so that the active centre region (indicated by the dotted circle) is accessible to OH' ions but not H^+ ions from the left (inside organelle), and to H^+ ions but not OH' ions from the right (cytoplasm side of organelle). The active centre, like that of phosphokinases in general, is assumed to be relatively inaccessible to water as water. To illustrate the hydrolytic activity of the system, the OH' ion is depicted as diffusing from left to right and finally combining at the active centre region with the terminal phosphorylium (P^+) derived from the ATP (ADP—O′—P^+) giving inorganic phosphate (POH) and ADP having a terminal ionized oxygen (ADP—O′), assuming the right-hand phase to be at about *p*H 7 and at electrical neutrality. The elegant conception of the transfer of phosphoryl as phosphorylium ion is due to Lipmann[21]. The system, of course, catalyses hydrolysis equilibrium, and the reverse or phosphokinetic activity of the 'ATPase' is indicated by the single barbs on the arrows of Fig. 1. In the case of the phosphokinetic activity, the OH' ion is depicted as passing down a free-energy gradient towards the left from an inorganic phosphate group (POH) that passes to the active centre region from the right. The phosphorylium ion (P^+), created by the withdrawal of the OH', is attacked by the negative atom ($-R'$) in the active centre region, and the phosphorylium ion is then donated to the terminal oxygen of ADP—O′ to give ATP. The chemi-osmotic coupling hypothesis depends thermodynamically on the fact that in such an anisotropic ATPase system, the electrochemical activity of the water at the active centre ($[H_2O]_c$), which determines the poise of the hydrolysis equilibrium in the ATP/ADP system, would be given, not by the product of $[H^+] \times [OH']$ in the aqueous phases L or R, but by the product $[H^+]_R \times [OH']_L$ (where [] stands for electrochemical activity, and R and L for right- and left-hand phases respectively). The ratio of the electrochemical activity [ATP]/[ADP] (including all ionic forms) can be raised, consequently, and the ATPase activity can be reversed to give an ADP phosphokinase activity proportional to the lowering of $[H_2O]_c$, in accordance with the mass-action law for hydrolysis equilibrium, written to include the elements of water as follows:

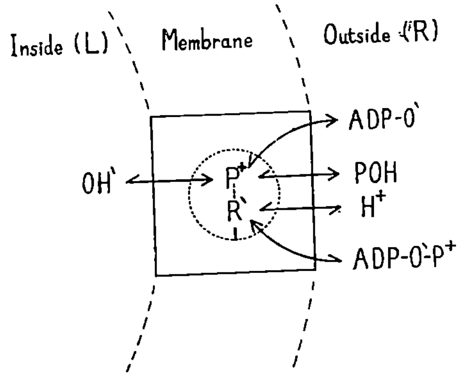

Fig. 1. Anisotropic reversible 'ATPase' system located in an ion-impermeable membrane between aqueous phases *L* and *R*

$$\frac{[ATP]}{[ADP]} = \frac{[P]}{K_1[H_2O]_c} \qquad (1)$$

The electrochemical activity of a component in a certain place defines absolutely the escaping tendency of the particles of the component due both to the chemical and to the electrical pressure to which the particles are subject in that place at equilibrium. Since

$$K_2 = \frac{[OH']_L \times [H^+]_L}{[H_2O]_L} \tag{2}$$

and K_2 is independent of the medium because we are using electrochemical activities, we can describe the electrochemical activity of the water at the active centre of the 'ATPase' system as follows:

$$[H_2O]_c = [H_2O]_{aq.} \times \frac{[H^+]_R}{[H^+]_L} \tag{3}$$

where $[H_2O]_{aq.}$ stands for the electrochemical activity of water in the aqueous physiological media of phases L or R, and is equivalent to about 55·5 M water.

By the definition of the electrochemical activity:

$$\frac{[H^+]_L}{[H^+]_R} = 10^{pH_{R-L}} \times 10^{(mV._{L-R})\frac{F}{2303\,RT}} \tag{4}$$

where pH_{R-L} is the pH of phase R minus that of phase L; $mV._{L-R}$ is the membrane potential in millivolts, positive in phase L; R is the gas constant; F is the faraday; and the factor $\frac{F}{2303\,RT}$ is approximately 1/60. It can be seen from equation (4) that the ratio $[H^+]_L/[H^+]_R$ is multiplied by a factor of 10 for each pH unit more negative on the left, relative to the right, and for each 60 mV. membrane potential, positive on the left. Equations 1 and 3 show that the ratio [ATP]/[ADP] at equilibrium is determined by $[H^+]_L/[H^+]_R$ as follows:

$$\frac{[ATP]}{[ADP]} = \frac{[P]}{K_1[H_2O]_{aq.}} \times \frac{[H^+]_L}{[H^+]_R} \tag{5a}$$

When the right-hand phase (representing the cytoplasm) is the region of the zero or reference potential, the electrochemical activity ratio of total ATP to ADP will be nearly the same as the corresponding concentration ratio, and [P] will correspond approximately to the inorganic phosphate concentration. Thermodynamic data[22] show that at pH 7 and at physiological temperatures the 'hydrolysis constant' as usually defined or the product $K_1[H_2O]_{aq.}$ is approximately 10^5; and when [P] is at the physiological level of 10^{-2} M, equation (5a) can be written:

$$\frac{[ATP]}{[ADP]} \simeq 10^{-7} \frac{[H^+]_L}{[H^+]_R} \tag{5b}$$

Thus, the [ATP]/[ADP] equilibrium can be poised centrally through the 'anisotropic 'ATPase' by making the ratio $[H^+]_L/[H^+]_R$ about 10^7. Equation 3 shows that this could be done, for example, by poising the left side 2 pH units below and 300 mV. above the right side. Such is the basic thermodynamic conception of the mechanism of reversal of the 'ATPase' activity. In kinetic terms, the reversal of the 'ATPase' activity can be understood by regarding the electrochemical activity gradient of hydrogen and hydroxyl ions across the active centre region of the 'ATPase' as the cause of the donation of the phosphorylium ion to the negative acceptor atom ($-R'$) by the simultaneous withdrawal of an OH' ion from the inorganic phosphate down a steep gradient to the left and of an H^+ ion from $-R$H to the right to ionize $-R$H or to prevent H^+ from competing with phosphorylium ion for the acceptor $-R'$. Dehydration is accomplished by using the high $[H^+]$ region as a sink for OH' and the high $[OH']$ region as a sink for H^+. It should be understood that the phosphorylation of ADP can be strictly described as dehydration only when the standard state is less than pH 6 (see Lipmann[21]). Since, however, the hydrogen atom of the terminal hydroxyl group of ADP, involved in phosphorylation, is dissociated reversibly as an H^+ ion, when the standard state is taken as pH 7, the phosphorylation process is mainly that of dehydroxylation. From the kinetic point of view, the fundamental processes involved are dehydroxylation + deprotonation, or dehydroxylation. It is relevant to note that phosphorylation is not directly caused by raising $[H^+]$, but is due to depression of $[OH']$. For this reason, the hydrogen ion depicted in phase R of Fig. 1 (and correspondingly in Figs. 2 and 3) is shown as equilibrating with the active centre region of the 'ATPase' system, but not as being withdrawn stoichiometrically in relation to the withdrawal of OH'.

The second basic feature of the chemi-osmotic coupling conception is the electron and hydrogen translocation system, which is assumed to create the gradient of electrochemical activity of H^+ and OH'. Unlike the conception of the anisotropic 'ATPase', the idea of the anisotropic o/r system is not new, but stems from the work of Lund[23], and Stiehler and Flexner[24], and was first stated explicitly by Lundegårdh[25] more than 20 years ago. Lundegårdh's idea was more exactly defined in relation to ion transport by Davies and Ogston[26], and was elaborated by Conway[27]. It has been excellently reviewed by Robertson[28].

Fig. 2 illustrates how the electron transfer can affect the ratio $[H^+]_L/[H^+]_R$. The electron translocation and 'ATPase' systems are depicted as being placed in opposition in a charge-impermeable membrane. The hydrogen ions generated on the left and the hydroxyl ions generated on the right by the electron translocation system dehydrate ADP and inorganic phosphate (now simply denoted by P) to form ATP by withdrawing hydroxyl ions to the left and hydrogen ions to the right through specific translocation paths in the 'ATPase' system as described here. Conversely, of course, the effect of the back pressure of ATP hydrolysis is to force the o/r system towards reduction on the left (inside the

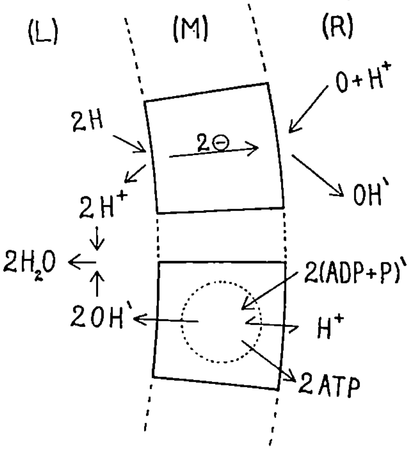

Fig. 2. Electron transport system (above) and reversible 'ATPase' system (below) chemiosmotically coupled in a charge-impermeable membrane (M) enclosing aqueous phase L in aqueous phase R

organelle). Note that the stoichiometry is 2 ATP per O, as in succinate oxidation by mitochondria. As shown in this simple diagram, the dehydrating force driving the phosphokinetic activity of the 'ATPase' system would be due largely to the chemical potential differential of the H^+ and OH' ions across the membrane, which would have to show as a *p*H difference of some 7 units across the membrane, acid on the left when the [ATP]/[ADP] equilibrium was poised centrally (see equations (5*b*) and (4)). We assume, however, that exchange diffusion carriers, as defined by Ussing[29], are present in the membrane and that they will allow strictly coupled one-to-one exchange of H^+ against K^+ or of OH' against Cl', for example. The *p*H differential would thus tend to be reduced to a relatively small figure and would be equivalently replaced by a membrane potential as described by equation (4).

When the oxido-reduction and phosphorylation systems are in chemi-osmotic equilibrium, one ATP molecule will be produced per electron translocated across the membrane. The relationship between the *o*/*r* potential span (ΔE) of the electron and hydrogen translocation system and the poise of the [ATP]/[ADP] equilibrium will be given as follows:

$$\frac{[\mathrm{ATP}]}{[\mathrm{ADP}]} = \frac{[\mathrm{P}]}{K_1[\mathrm{H_2O}]_{\mathrm{aq.}}} \times 10^{\frac{\Delta E.F}{2303\,RT}} \qquad (6a)$$

or approximately:

$$\frac{[\mathrm{ATP}]}{[\mathrm{ADP}]} = \frac{[\mathrm{P}]}{10^5} \times 10^{\Delta E/60} \qquad (6b)$$

ΔE being in millivolts. It should be understood that ΔE, as defined here, is equivalent to the free-energy change in the electron-translocating system per electron translocated. Assuming that ATP synthesis were occurring when the [ATP]/[ADP] ratio was poised centrally at *p*H 7 and in the presence of 10^{-2} *M* inorganic phosphate, the *o*/*r* span, ΔE, would have to be about 420 mV. This, of course, being the equilibrium potential, represents the minimum *o*/*r* span of the electron and hydrogen translocation system required to drive ATP synthesis under the conditions specified above. The span between the succinate–fumarate couple and oxygen at 76 mm. mercury pressure is about 750 mV.—well above the minimum ΔE of 420 mV.

In practice, the mitochondrial or chloroplast membrane across which the chemi-osmotic coupling may be organized would allow a certain amount of ion leakage, and the translocation paths for H^+ and OH', connecting the internal and external phases (*L* and *R*) with the active centre region of the 'ATPase', would not be expected to have absolute specificity for H^+ and OH' respectively. Consequently, equations (6*a*) and (6*b*) would represent the practical state of affairs in the most tightly coupled systems. On 'loosening' the membrane system, or if 'uncoupling' were effected by catalysing the equilibration of H^+ and charge across the lipid of the membrane with reagents like dinitrophenol or salicylate, the relationship between the poise of the [ATP]/[ADP] ratio and ΔE in the steady state would be described by the inequality:

$$\frac{[\mathrm{P}]}{K_1[\mathrm{H_2O}]_{\mathrm{aq.}}} \leqslant \frac{[\mathrm{ATP}]}{[\mathrm{ADP}]} \leqslant \frac{[\mathrm{P}]}{K_1[\mathrm{H_2O}]_{\mathrm{aq.}}} \times 10^{\frac{\Delta E.F}{2303\,RT}} \quad (6c)$$

The outer terms of equation (6*c*) represent the extreme values of the [ATP]/[ADP] ratio from complete uncoupling on the left to complete coupling on the right.

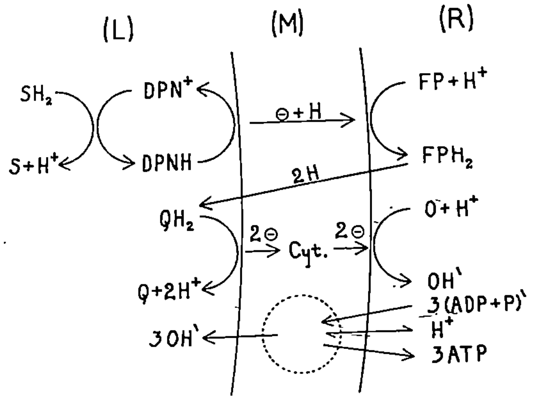

Fig. 3. Diagram of chemi-osmotic system for coupling phosphorylation to the oxidation of substrate (SH_2) through DPN, *FP* (tentatively identified with flavoprotein), *Q* (tentatively identified with a quinone) and the cytochromes (*Cyt.*). The other conventions are as in Figs. 1 and 2

Fig. 3 shows, in principle, a rather fuller description of oxidative phosphorylation, in which I have included the *o*/*r* components *FP* and *Q*, tentatively identified with flavoprotein and quinol–quinone systems respectively. The main aim is to illustrate how a stoichiometry of 3 ATP per O can readily be obtained for substrate (SH_2) oxidation through DPN, by the obligatory transport of one (net) hydrogen atom inwards per O, owing to the spatial arrangement of the electron and hydrogen transfer chain and the zero, one, or two hydrogen-transfer characteristics of the carriers involved. In this system, the span of both parts of the *o*/*r* chain across the membrane would have to be poised against the same ratio $[H^+]_L/[H^+]_R$ at equilibrium, according to equation (5*a*). Using the conventions of Dixon[2], the $-\Delta F$ value for the DPN/DPNH couple at about *p*H 5 would be some 3,000 cal. and the $-\Delta F$ for *FP* (corresponding to an E'_0 (*p*H 7) of -60 mV.) (ref. 30) would be about 17,000 cal., giving a span of 14,000 cal.; equivalent to a ΔE of 600 mV. Assuming the $-\Delta F$ of the *Q* system to be about 24,000 cal., corresponding to an E'_0 (*p*H 7) of $+100$ mV., as in the ubiquinone system[31], the span from the *Q* system to oxygen at 76 mm. mercury pressure would be equivalent to a ΔE of about 750–100 = 650 mV. The tendency of the two *o*/*r* values to drift together and the exact magnitude of the composite *o*/*r* potential would, of course, depend on many factors that it would be premature to consider here. It will suffice to point out at present that the value of 600–650 mV. for ΔE is appropriately above the required minimum of 420 mV. and that the proposed system is thus in accord with the thermodynamic facts.

The above basic chemi-osmotic conception can be applied to photosynthetic phosphorylation with the difference that the electron and hydrogen translocation are seen as being driven, not by the affinity of oxygen for the hydrogen atoms and electrons, but by the energy of the absorbed photons, according to the type of mechanism described by Calvin[9b]. It can readily be shown that in a chemi-osmotically coupled system for non-cyclic photophosphorylation, the photon-activated movement of 2 electrons and 2 hydrogen atoms outwards through the membrane of the grana would produce one O_2 and 2 ATP molecules. Similarly, in non-cyclic photophosphorylation, the skew of $[H^+]_L/[H^+]_R$, and thus the synthesis of ATP, could be caused by the photon-activated passage of equal numbers of hydrogen atoms and electrons in opposite directions across the membrane of the grana or chromatophores.

The facts that were listed at the beginning of this article as being difficult to reconcile with the orthodox chemical conception of the mechanism of coupling phosphorylation to electron and hydrogen transfer can now be reconsidered in relation to the chemi-osmotic coupling hypothesis: (*a*) The elusive character of the 'energy-rich' intermediates of the orthodox chemical coupling hypothesis would be explained by the fact that these intermediates do not exist. (*b*) According to the chemi-osmotic coupling hypothesis, the differential of the electrochemical activity of the hydrogen and hydroxyl ions across the membrane, generated by electron transport, causes the specific translocation of hydroxyl and hydrogen ions from the active centre of the so-called ATPase system, thus effectively dehydrating ADP + P. The charge-impermeable membrane would therefore be an absolute requirement for tight coupling. (*c*) Coupling would be expected to vary with the extent of leakiness or strain in the membrane, determined, of course, by the osmotic and electrical stress. (*d*) The internal components of mitochondria such as DPN would tend to be reduced by the high electrochemical activity of H^+ caused by hydrolysis of external ATP, which would withdraw OH' ions from the inside in competition with the electron-transport system. This effect would be accentuated by oxidation of succinate (which would raise the internal value of $[H^+]$) but not, of course, by substrates such as acetoacetate that directly oxidize DPNH. (*e*) Uncoupling would be caused by lipid-soluble reagents, such as DNP, salicylate, azide, and ammonia, catalysing equilibration of H^+ or OH' and charge across the membrane. (*f*) According to the chemi-osmotic type of hypothesis, the coupling of phosphorylation to electron and hydrogen translocation would cause considerable electrical and mechanical stress in the membrane across which coupling was effected. Complex swelling and shrinkage effects would therefore be expected to accompany the activity of the system.

It is evident that the basic features of the chemi-osmotic coupling conception described here and elsewhere[20] are in accord with much of the circumstantial evidence at present available from studies of oxidative and photosynthetic phosphorylation. This simple hypothesis also has the merit that it represents the result of carrying to its logical conclusion the present trend towards recognizing the equivalent status of supramolecular and molecular features in the channelling of chemical processes in living organisms[18]. Further experimental support for the chemi-osmotic coupling conception may best be sought by attempting to characterize separately each of the three hypothetical basic elements of which the system is thought to be built: (1) the anisotropic 'ATPase' system which I have defined above; (2) the anisotropic *o/r* system of the type originally defined by Lundegårdh; (3) the specific charge-impermeable membrane in which the systems 1 and 2 are supposed to be orientated in opposition. Work along these three lines is proceeding in my laboratory.

In the exact sciences, cause and effect are no more than events linked in sequence. Biochemists now generally accept the idea that metabolism is the cause of membrane transport. The underlying thesis of the hypothesis put forward here is that if the processes that we call metabolism and transport represent events in a sequence, not only can metabolism be the cause of transport, but also transport can be the cause of metabolism. Thus, we might be inclined to recognize that transport and metabolism, as usually understood by biochemists, may be conceived advantageously as different aspects of one and the same process of vectorial metabolism[20a,32].

I am indebted to the Nuffield Foundation for grants in aid of this work. It is also a pleasure to thank Dr. G. D. Greville, Prof. D. Keilin, Dr. R. Hill, Dr. Jennifer Moyle, Sir Rudolph Peters, and other colleagues for very helpful discussion and criticism.

TWO SEROLOGICALLY ACTIVE TRISACCHARIDES ISOLATED FROM HUMAN BLOOD-GROUP *A* SUBSTANCE

By I. A. F. LISTER CHEESE and PROF. W. T. J. MORGAN, C.B.E., F.R.S.

Lister Institute of Preventive Medicine, Chelsea Bridge Road, London, S.W.1

IT is recognized that the serological characters of human blood-group specific mucopolysaccharides are due to relatively simple carbohydrate structures[1]. A direct means of studying these characters in detail consists in the examination of hydrolysis fragments which retain a measure of the serological activity of the intact substance.

Côté and Morgan[2] reported the isolation of five disaccharides from group *A* substance and showed that one of them, believed to be *O*-α-*N*-acetylgalactosaminoyl-(1 → 3)-galactose, was serologically active and inhibited the agglutination of *A* cells both by human *iso*-agglutinins and by an *A* specific reagent prepared from lima bean. They concluded that the disaccharide had a structure more closely associated with *A* specificity than any that had then been identified. This work has been extended and two trisaccharides showing *A* specificity have been isolated and are now described.

Blood-group *A* substance (22 gm.) was heated as a 2 per cent w/v solution in 0·1 *N* hydrochloric acid at 100° for 30 min. The solution was cooled and thoroughly dialysed to recover material of low molecular weight. This procedure was repeated on the indiffusible material, subsequent hydrolysis periods being 0·5 hr., 1 hr. and 2 hr. After removal of acid by passage through 'Deacidite *E*' (carbonate form) the diffusible material was broadly fractionated on a charcoal–'Celite' column into monosaccharides, disaccharides and higher oligosaccharides.

Higher oligosaccharides (1·5–2 gm.) were fractionated further on a charcoal–'Celite' column (70 cm. × 3·6 cm.) by gradient elution with aqueous ethanol (30 per cent v/v → 5 l.). Fractions of about 40 ml. were collected and examined by chromatography. All fractions were found to contain mixtures of sugars, and one group only (fractions 106–118) has so far been resolved. These fractions contained little of substances other than the two major trisaccharides now to be described. The material (230 mgm.) was fractionated by paper chromatography (solvent *A*, butanol–pyridine–water, 3 : 1 : 1, Whatman 3 *MM* paper) to yield trisaccharide I (28 mgm.) and trisaccharide II (40 mgm.). Further purification was carried out by eluting these materials from charcoal columns.

Trisaccharide I $[\alpha]_D + 147°$ was homogeneous by the criteria of paper chromatography (R_{lactose}: 0·97, in solvent *A*, Whatman 3 *MM* paper) and paper ionophoresis (M_G: 0·39, in borate buffer, *p*H 10). With benzidine-trichloroacetic acid[3] spray reagent it gave a yellow-brown colour similar to that given by *O*-β-galactosyl-(1 → 4)-*N*-acetylglucosamine. It reacted only feebly with the Ehrlich reagents of Partridge[4]. Complete acid hydrolysis yielded galactose, galactosamine and glucosamine, which were identified chromatographically. Determination of the sugars by Wilson's method[5] showed them to be present in equimolecular amounts. A preparation of enzyme from *Trichomonas foetus*[6] which destroyed the serological activity of *A* substance hydrolysed the trisaccharide to galactose and the two *N*-acetylated amino-sugars, but at an intermediate stage in the hydrolysis it was possible to detect a Morgan–Elson-negative saccharide indistinguishable chromatographically from *O*-β-galactosyl-(1 → 4)-*N*-acetylglucosamine, which had also been identified by Côté and Morgan[2] as a constituent unit in *A* substance.

Oxidation of the trisaccharide (0·06 m*M*) after reduction with sodium borohydride was carried out in 0·4 m*M* periodate, *p*H 3–5 at room temperature. Selective oxidation of the alcohol terminal takes place under these conditions[7]. The release of formaldehyde—1·00 mole per 590 gm. sugar—was complete within 10 min. A similar rapid and complete liberation of 1 mole proportion of formaldehyde was observed in the oxidation of reduced *O*-β-galactosyl-(1 → 4)-*N*-acetylglucosamine.

The trisaccharide was partially hydrolysed with *N* sulphuric acid at 100° for 36 min. and the hydrolysate examined by paper chromatography (solvent *A*). Among the products, which included the three constituent sugars and a little unchanged trisaccharide, there were found two reducing substances indistinguishable from *O*-α-*N*-acetylgalactosaminoyl-(1 → 3)-galactose and *O*-β-galactosyl-(1 → 4)-*N*-acetylglucosamine. It is concluded that trisaccharide I is most probably *O*-α-*N*-acetylgalactosaminoyl-(1 → 3)-*O*-β-galactosyl-(1 → 4)-*N*-acetylglucosamine.

In serological tests the trisaccharide was found to inhibit not only the agglutination of *A* cells by the common anti-*A* reagents, but also the lysis of sheep cells by rabbit anti-*A* immune serum and complement. *O*-α-*N*-acetylgalactosaminoyl-(1 → 3)-galactose alone of the disaccharides tested showed the same properties (Table 1).

Trisaccharide II $[\alpha]_D + 136°$ was homogeneous by chromatographic criteria (R_{lactose}: 1·10, in solvent *A*, Whatman 3 *MM* paper; M_G: 0·39, in borate buffer, *p*H 10). Both the benzidine-trichloroacetic acid spray reagent, with which it gave a dark

Table 1. AMOUNTS OF *A* SUBSTANCE AND SUGARS GIVING INHIBITION OF (*a*) HUMAN *ISO*-AGGLUTININS AND (*b*) RABBIT ANTI-*A* SHEEP CELL HÆMOLYSINS

Substance	Minimum amount of substance giving inhibition (μgm./0·1 ml.)	
	a	*b*
Human *A* substance	0·04	0·01
N-acetylgalactosamine	> 1,000	> 1,000
α-Methyl-*N*-acetylgalactosaminide	500	500
O-α-*N*-acetylgalactosaminoyl-(1→3)-galactose	60	250
O-α-galactosyl-(1→3)-galactose	> 1,000	> 1,000
O-β-galactosyl-(1→3)-*N*-acetylglucosamine	> 1,000	> 1,000
O-β-galactosyl-(1→4)-*N*-acetylglucosamine	> 1,000	> 1,000
Trisaccharide I	60	15
Trisaccharide II	60	30

greenish-brown colour, and the Ehrlich reagents, provided ready means of detecting the substance. The component sugars, identified and determined as for trisaccharide I, were galactose, galactosamine and glucosamine in equimolecular amounts. Hydrolysis with the enzyme preparation obtained from *T. foetus* gave galactose and the two *N*-acetylated aminosugars.

Trisaccharide II, partially hydrolysed with *N* acid and examined as described for trisaccharide I, gave the same three constituent sugars and *O*-α-*N*-acetylgalactosaminoyl-(1 → 3)-galactose. In place of *O*-β-galactosyl-(1 → 4)-*N*-acetylglucosamine there was found a Morgan–Elson-positive spot corresponding to *O*-β-galactosyl-(1 → 3)-*N*-acetylglucosamine.

Treatment of the substance with 0·05 *N* sodium carbonate at 18–20° for 30 min. yielded, apart from some unchanged trisaccharide, several 'direct' Ehrlich chromogenic substances and a reducing substance indistinguishable in both chromatography and ionophoresis from *O*-α-*N*-acetylgalactosaminoyl-(1 → 3)-galactose. The lability of the trisaccharide to alkali and the high alkalinity of the borohydride reagent renders unsatisfactory the determination of formaldehyde liberated after reduction and selective oxidation with periodate.

Trisaccharide II also possessed the capacity to inhibit a number of anti-*A* reagents, and it is noteworthy that in tests for inhibition of sheep cell hæmolysis, it was rather less active (Table 1) than trisaccharide I. Trisaccharide II is believed to be *O*-α-*N*-acetylgalactosaminoyl-(1 → 3)-*O*-β-galactosyl-(1 → 3)-*N*-acetylglucosamine.

The long-known and unique association of group *A* antigens with both *iso*-agglutinins and heterophile (Forssman) antibodies[8] seems to depend on the similar specificities of these antibodies. It seems probable that they correspond to different but overlapping parts of the same carbohydrate structure, the common part being represented by *O*-α-*N*-acetylgalactosaminoyl-(1 → 3)-galactose. This relationship will be discussed in more detail elsewhere. The association of each of the trisaccharides with these two serologically different reagents strengthens the belief that they arise from specific determinant groups in the macromolecule rather than from latent structures which are not directly concerned with specificity.

We wish to thank the Nuffield Trust for financial support. One of us (I. A. F. L. C.) thanks the Lister Institute for a studentship.

THE FEULGEN-STAINED SOMATIC CELL NUCLEUS AS A HOMOGENEOUSLY ABSORBING OBJECT

By DR. SIMON IVERSEN

Cancer Research Department, Royal Beatson Memorial Hospital, Glasgow

IT is generally accepted that a somatic cell nucleus doubles its genetic material between two consecutive divisions, that the deoxyribonucleic acid (DNA) content of the nucleus is identical with, or at least proportionate to, the nuclear amount of genetic material; further, that the Feulgen reaction is specific for the nuclear DNA, and finally, that the intensity of the Feulgen stain is proportionate to the amount of DNA. So by measuring the intensity, E, of the Feulgen stain of a nucleus and multiplying E with the squared nuclear diameter, D^2, it is imagined that a direct measure of mass is obtained. This is seemingly corroborated by the finding by numerous investigators that the ED^2 values from haploid, diploid, tetraploid and octoploid nuclei show modal distributions with modes at (approximately) 1 ×, 2 ×, 4 × and 8 × ED^2. In this article it will be shown that ED^2 is not a direct measure of mass.

The interpretation of ED^2 as a direct measure of mass would be correct if the nuclei were homogeneously absorbing objects, that is, objects in which the absorbing particles are completely randomly distributed, non-interacting, and retaining their size and shape. For such a system the absorbance, E, is a linear function of the number of absorbing particles, C, the path-length, L, and the molecular absorbancy index ε, which latter can be omitted when dealing with relative amounts of the same compounds. As the concentration is mass per volume (M/V) and as the path-length may be taken as being equal to the diameter, the absorbance of a homogeneously absorbing sphere will be:

$$E = \frac{MD}{1{\cdot}33\pi r^3} = 1{\cdot}92\ MD^{-2} \qquad (1)$$

So by plotting E against D^{-2} a straight line starting in origin and with slope of 1·92 M should be obtained. As a paradigm of the straight line course, Alfert's[1] data on rat liver nuclei have been plotted this way in Fig. 1. From Table 1, where the results of regression analyses of different investigators' published data are given, it is seen that in seven out of nine cases the numerical value of the constant a deviates significantly from zero. This indicates that the relationship between E and D^{-2} most frequently is:

$$E_m = a + bD^{-2} \qquad (2)$$

If the nuclei were homogeneously absorbing objects the occurrence of the constant a would mean that the measured absorbance, E_m, is the sum of the absorbance of the compound in question, E_r, and a constant non-specific absorbance, thus:

$$E_m = E_r + a \qquad (3)$$

Table 1

	Cell type	No.	$y = a + bx^{-2}$	$P\{t_a\}$	
Alfert* *et al.*	Diploid (liver)	30	$E = -0\cdot026 + 15\cdot67\,D^{-2}$	0·0025 – 0·001	(3*a*)
	Tetraploid (liver)	30	$E = 0\cdot042 + 27\cdot36\,D^{-2}$	$\leqslant$ 0·0005	(3*b*)

Swift	Neuron	10	$E = 0\cdot014 + 15\cdot21\,D^{-2}$	0·05 – 0·025	(3*h*)
	Liver	10	$E = 0\cdot163 + 9\cdot35\,D^{-2}$	$\leqslant$ 0·0005	(3*i*)

* Dr. Alfert and Dr. Pasteels have kindly sent me their original data.

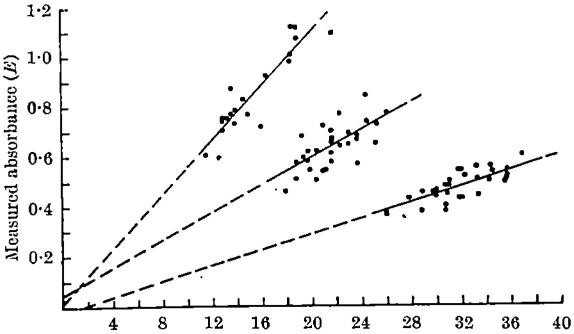

Fig. 1. Alfert's (1955) data for rat liver nuclei

The mass of the compound in question will therefore be:

$$E_r D^2 = (E_m - a)D^2 \tag{4}$$

and from equation (2):

$$(E_m - a)D^2 = (a + bD^{-2} - a)D^2 = b \tag{4a}$$

The mass remains constant, as is also obvious in the case of equation (1), where:

$$E_m D^2 = E_r\,D^2 = 1\cdot92\,M \tag{5}$$

However, some investigators have claimed that their photometric data show synthesis to occur. Here it will be demonstrated that the reason for these claims seems to be that the mass has been calculated as $E_m D^2$ instead of $E_r D^2$.

Thus Swift[7] claims to have demonstrated that synthesis occurs in embryonic mouse liver nuclei. The majority of his data are given as histograms showing the number of nuclei of a given nuclear 'mass'. He also gives, however, the raw data of E and D for 10 measurements on embryonic mouse liver, which presumably are representative for the rest of the measurements on this tissue. From Fig. 2 where E is plotted against D^{-2} it is seen that the data conform to a straight line course with a significant y-intercept (equation 3*i*). If the mass in this case is calculated as $E_m D^2$ and plotted against D the resulting curve, shown in Fig. 3, might be thought to show that the mass increased with increasing diameter, that is, that synthesis does take place. The correctly calculated mass would, however, be $E_r D^2 = b$. The mass remains constant, indicated in Fig. 3 by line B, and no synthesis occurs.

Walker and Yates[8] measured the light absorption in the ultra-violet and visible regions of living and Feulgen-stained nuclei of chick heart tissue cultures at known times after mitosis. The total amount of absorbing matter, which for the sake of convenience here will be called 'mass', was calculated as $E_m D_T{}^2$, where D_T is the nuclear diameter at time T after mitosis. It should be emphasized that a given nucleus was measured at only one time after mitosis, the same nucleus was not measured at known different times after mitosis, from which it follows that the additional information about the intermitotic age of the nuclei does not make these measurements different in any way from measurements on nuclei of unknown intermitotic age. In both cases the relation between

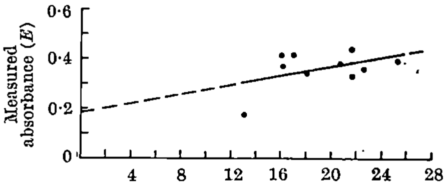

Fig. 2. Swift's (1950) data for embryonic mouse liver nuclei

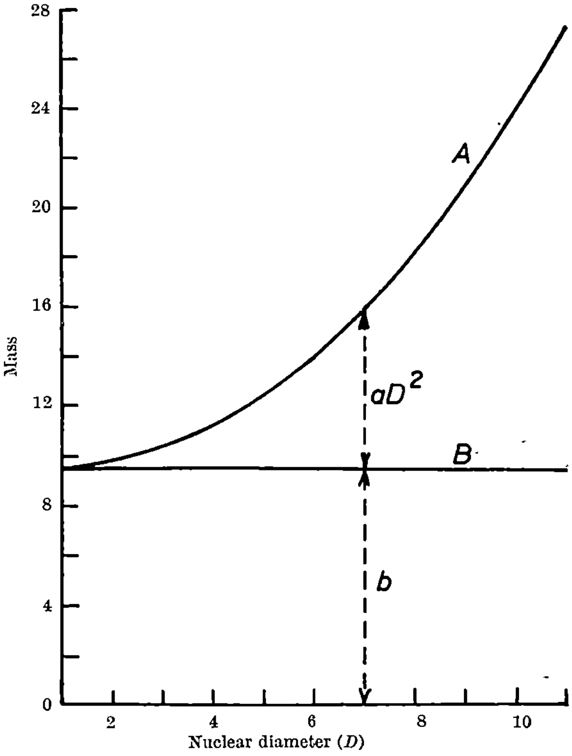

Fig. 3

E and D^{-2} is completely independent of time, inhomogeneity of the population and non-random selection.

Walker and Yates plot mass against time after mitosis. Obviously the course of such curves must be determined by the way in which the nuclear diameter alters with time. If we assume in conformity with the vast majority of data on growth[2] that the increase in geometrical dimensions (= 'growth') of a nucleus is an exponential function of time, or, in other words, that the diameter is increasing in time with a rate which is proportional to the diameter, we have:

$$D_T \sim e^{KT} \qquad (6)$$

Thus plotting E_mD^2 (= 'mass') against time would be equivalent to plotting E_mD^2 against $\ln D_T$. In Figs. 4 and 5, $\ln E_mD^2$ is plotted against time, the experimental points being read off Walker and Yates's graphs of E_mD^2 against T for the total ultra-violet absorption and for the Feulgen-stained material, respectively. As is seen from these figures, the regression lines which have the equations:

$$\ln E_mD^2 = 1{\cdot}903 + 0{\cdot}035\,T \text{ for Fig. 4}$$

and

$$\ln E_mD^2 = 1{\cdot}393 + 0{\cdot}077\,T \text{ for Fig. 5}$$

fit the data well.

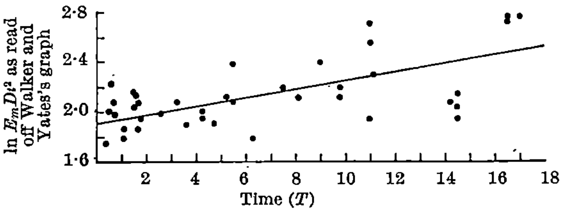

Fig. 4. Walker and Yates's (1952) data for the total Feulgen stain intensity

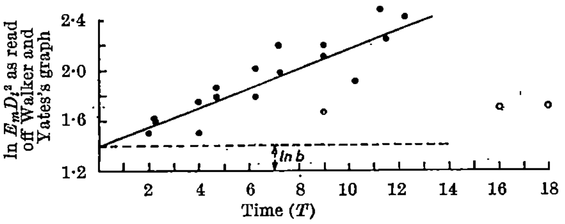

Fig. 5. Walker and Yates's (1952) data for the total ultra-violet absorbance

A plot of $\ln E_mD^2$ against $2KT$ ($\simeq \ln D_T{}^2$) would also result in a straight line, but having half the slope of the lines in Figs. 4 and 5. Consequently, a plot of E_mD^2 against D^2 would result in curves which were upwards concave and having y-intercepts of 6·69 and 4·01, respectively. The correctly calculated 'mass' would therefore be:

$$E_mD^2 = (a + bD^{-2} - a)D^2 = b \qquad (7)$$

where $D^2 \sim e^{2KT}$, giving constant masses of 6·69 and 4·01 respectively. It should be pointed out that even if the nuclear growth were not exponential in time, but was another function of time, a linear transformation of such function would lead to similar results.

The claims of having demonstrated, on the basis of photometric data, that synthesis takes place during interphase cannot therefore be said to be proved. If homogeneity is assumed and if the data conform to equations (1) or (2) an increase of M is indeed an impossibility.

This is also evident from the following argument: if the chromosome number ($\sim$ 'mass') doubles during interphase, a tetraploid nucleus at the beginning of the interphase would have the same mass as a diploid nucleus at the end of the interphase. We would therefore expect, if the nuclei were homogeneously absorbing objects, that the absorbancy of nuclei of different ploidy, when plotted against D^{-2}, would all fall on the same straight line. But as seen from Fig. 1, and from Table 1, straight lines with definitely different slopes are obtained, giving different absorbances for nuclei of identical geometrical dimensions and (presumably) mass.

It could then be argued that the doubling of the nuclear genetic material takes place when the nuclei are in a phase which is not represented in the population of measured nuclei, that is, during the mitotic process. The nuclear interphase mass (= Feulgen stain intensity) would remain constant and if the absorbing particles were randomly distributed, E would be linear with D^{-2}, as observed. There are, however, two reasons for not accepting this interpretation. The first is that chemical estimation of DNA (ref. 5) shows the synthesis to occur during the interphase ; and the other is that in fixed nuclei the Feulgen-stained material (and nucleoli) is distributed in a peripheral zone[3,4], the peripheral edge of which cannot be distinguished from the nuclear membrane. Therefore, calculation of nuclear mass from photometric data is not possible until such parameters as thickness, possible concentration gradient of the stained particles in this zone, and possible orientation of the absorbing particles in this zone can be estimated.

Further, if the population of measured nuclei is representative of the true population of interphase nuclei, an assumption which is tacitly granted, and if the mitoses in the parent tissue do not occur synchronously, but randomly, and if all the nuclei follow the same basic growth equation, then the probability of including any given nucleus of any given interphase age in the measured population is constant and identical for all the nuclei irrespective of the type of the underlying kinetic equation. If ED^2 were a direct measure of mass we should not expect, therefore, to observe a modal distribution of these values.

We must conclude, therefore, that ED^2 is not a direct measure of mass and the seemingly good agreement between these values and chromosome numbers must therefore be due to some other cause.

I wish to thank Dr. P. R. Peacock for valuable discussion and for reading and criticizing the manuscript.

This investigation was supported by a full-time grant from the British Empire Cancer Campaign.

REGENERATION OF ELEMENTS OF DONOR ORIGIN IN ORTHOTOPICALLY GRAFTED SKIN FOLLOWING THE HOMOGRAFT RESPONSE

By Dr. J. K. DINEEN and Dr. ALEKSANDER SZENBERG

Walter and Eliza Hall Institute of Medical Research, Melbourne

THE work reported here arose out of attempts to induce immunological tolerance of orthotopic skin grafts in adult inbred mice by the administration of 6-mercaptopurine (6-MP). Groups of recipient mice were treated with 0·25, 0·50, 1·0, 1·5 and 2·0 mgm. of 6-MP daily for 7–10 days before grafting, and for several days thereafter. In order to provide a more generalized antigenic stimulus, several groups were also injected intraperitoneally with isolated spleen cells of the graft-donor strain during treatment with 6-MP. However, the mean survival-time for *C57B*1 homografts on *C3H* mice was only prolonged by 3 days by these procedures and this effect was only observed in recipients in which gross lymphoid involution had been produced by toxic doses of 6-MP. The survival of *C3H* skin grafted on to *C57B*1 mice was not prolonged. The results of these experiments are in agreement with the findings of Meeker *et al.*[1]. They failed to observe prolongation of homograft survival in mice treated with 6-MP. Similar experiments in which grafts were exchanged between the closely related *AKR*, and *C3H* mice treated with 6-MP, gave the same negative result. In the course of this work, we observed in a number of the mice which had been pre-sensitized with spleen cells that homografts survived indefinitely if the removal of the plaster protective bandages was delayed until 16–17 days after grafting. This indefinite survival occurred in mice that had received 6-MP and in others which had not received the drug. The present article is concerned with this phenomenon of the apparent survival of skin homografts in specifically immunized mice.

In a typical experiment six *C3H* adult mice were each injected intraperitoneally three times during a 10-day interval with 20×10^6 *C57B*1 nucleated spleen cells and grafted with *C57B*1 skin by Medawar's technique 5 days after the third course of injections. A control group of 6 *C3H* adult male mice which were not treated received *C57B*1 grafts at the same time as the injected group. The protective bandages were removed from both control and treated animals 16 days after grafting. The grafts on the treated animals, though non-pigmented and showing no hair growth, were retained without gross change in appearance for an indefinite period. The grafts on the control animals had a similar appearance when the bandages were removed, but rapidly dried out on exposure to the air, and were afterwards completely rejected. The surviving grafts were retained for several months, although macroscopic pigmentation and normal hair growth did not occur. Similar results have been observed when skin homotransplants have been transferred to specifically treated animals in other strain-combinations (*C3H* and *C57B*1 grafts on appropriately immunized *AKR* mice). Attempts to extend this phenomenon to inter-species graft survival (rat skin on mouse, mouse skin transplanted to rats) have failed.

Although the response observed in *C3H* mice pretreated by injection of cells differs sharply from the response observed in untreated animals at 16 days this difference was not so apparent when the plaster bandage was retained intact for a further 4–5 days. A proportion of homografts remained intact on control recipients when the protective bandages were removed at 20 days. The possible explanation of this unexpected finding was sought by histological examination of the development of the homograft reaction in pretreated and untreated mice. Histological sections of grafts were prepared at 2-day intervals following the orthotopic transfer of *C57B*1 skin to treated and untreated *C3H* recipients. Two distinct kinds of cellular infiltration were observed in sections obtained from both treated and control animals. The more superficial band, predominantly polymorphonuclear, developed immediately below the epithelial layers of the grafted tissues and, concurrently, a deeper band of infiltrating polymorphs and lymphocytes demarcated the graft tissue from the panniculus carnosus of the host. The development of the destructive sub-epithelial infiltrate was an acute event in both treated and control mice. The only obvious difference in response in the two groups of animals was that the sub-epithelial accumulation of polymorphs was most intense in the treated group of mice at 4–6 days, while this response was delayed for 8–10 days in the control animals. The demarcating inflammatory response at the deeper level also developed at 4–6 days in treated animals, and at 8–10 days in the controls, but afterwards followed a more chronic course in both groups. By about the third week after grafting, the demarcating zone between graft and graft bed was characterized by a mononuclear infiltrate containing primitive reticulum cells, lymphocytes and plasma cells and fibroblastic elements. Few polymorphs were then evident in this zone. With the subsidence of the acute polymorph response, the graft epithelium began a process of regeneration which was essentially complete in 10 days; that is, 14–16 days after grafting in the treated group, and correspondingly later in that proportion of the control animals in which regeneration occurred, that is, at 18–20 days after grafting.

Perhaps the most significant feature of these findings is that the sub-epithelial infiltration of polymorphs did not recur on the regeneration of the epithelium in either group. This failure of the host to react against the newly established epithelium has usually been interpreted as indicating that the regeneration is by cellular elements wholly derived from the host. There are difficulties in accepting this view, and we have therefore considered three

Table 1. TRANSFER OF REGENERATED TISSUES

Strain of skin donor	Recipient strain and No.*	Time of transfer of regenerating graft and strain of recipient	Strain of donor of challenge graft	Histological appearance of challenge graft at 6 days—classification of immunological response
*C*57*B*1	10 × *C*3*H*	*C*3*H*—16 days	*C*57*B*1	*Epithelial layers*—some areas of old necrotic epithelium remaining; 1–4 layers of regenerating epithelial cells showing mitotic activity. *Sub-epithelial infiltrate*—single lymphocytes and/or polymorphonuclear debris. *Demarcating infiltrate*—intense lymphocytic and fibroblastic with polymorphs mainly in and around the vessels. *Classification*—second set homograft response.
*C*57*B*1	6 × *C*3*H*	*C*57*B*1—17 days	*C*3*H*	As above.
*C*57*B*1	6 × *C*3*H*	*AKR*—16 days	*C*57*B*1	As above.
*C*57*B*1	4 × *C*3*H*	*AKR*—16 days	*C*3*H*	*Epithelial layers*—large areas of destroyed epithelium remaining; 1–2 layers of regenerating epithelium showing mitotic activity in remainder of grafts. *Sub-epithelial infiltrates*—as above. *Demarcating infiltrate*—as above. *Classification*—second set homograft response.
*C*57*B*1	4 × *AKR*	*AKR*—18 days	*C*57*B*1	*Epithelial layers*—epithelium completely destroyed; no regeneration observed. *Sub-epithelial infiltrate*—intense polymorphonuclear infiltration. *Demarcating infiltrate*—moderate polymorphonuclear, lymphocytic and fibroblastic; some plasma cells. *Classification*—second set homograft response.

* All recipient animals were injected intraperitoneally with 20 × 10^6 nucleated spleen cells of the skin donor strain three times during the 10-day period before grafting.

other possibilities. The failure of response might also be due to: (*a*) a change in the general immunological status of the host; (*b*) a change in the local immunological status of the host; or (*c*) failure of regenerating donor tissue to attain antigenic competence either by 'adaption' or by deletion of antigenic determinants followed by a process of local selection for survival. A change in the general immunological status of the host is excluded by the observation that a second set graft reaction is invoked in these animals by a second graft with the skin of the donor (*C*57*B*1) strain. The possibility that the graft has not regained antigenic competence of donor strain specificity can be experimentally tested. Transfer of the regenerated tissue to normal mice of the recipient (*C*3*H*) strain invokes a first set homograft reaction as judged both macroscopically and microscopically. It has not been possible to include as a control an equivalent area from a *C*3*H* mouse in which regenerating epithelium of known host origin has replaced the normal skin, but the validity of our observation is supported by the fact that mice having rejected the graft of regenerated tissue were afterwards able to reject a further *C*57 graft with a typical second set, accelerated reaction (Table 1).

This is *prima facie* evidence that a regenerating element in the transferred graft has donor (*C*57*B*1) specificity, and can sensitize the new recipient to give a second set response. It is quite unlikely that either sub-cellular antigenic material or a small proportion of surviving, but inert, epithelial cells of *C*57*B*1 provenance, protected in some way among regenerating host cells, could be responsible for this sensitization. The possibility that presensitization of the recipient mice might be 'adoptively'[2] acquired by the coincidental transfer of isologous, immunologically competent cells present in the regenerated tissue could be tested by transfer in a homologous system where the transferred lymphoid cells would not be expected to survive. Thus *C*57*B*1 grafts surviving on *C*3*H* mice have been transferred at 16 days to normal *AKR* mice (Table 1). A subsequent *C*57*B*1 graft on these animals stimulated a characteristic second-set graft response, while the appropriate control-*C*3*H* skin grafted on to normal *AKR* failed to induce a second-set graft reaction when these animals were grafted with *C*57*B*1 tissue later.

Confirmatory evidence that homograft survival in treated mice is related to regeneration of donor elements was obtained by X-irradiation of the donor tissue at a level (1,000 r.) which might be expected to suppress mitotic activity. The irradiation was done as soon as possible after removal of the skin from the donor, the graft being applied to the recipient immediately after irradiation. Despite delay in removal of the protective bandages for 16 days, such grafts were rejected, and this observation is in accord with the hypothesis that regeneration of some elements of donor origin are essential for the graft survival. If regeneration of the graft were wholly due to cellular elements derived from the host then it would be unlikely that moderate X-irradiation of the donor tissue would inhibit regeneration.

There is no doubt that host cells do invade the primary graft. Histologically there is evidence for the entry of connective-tissue elements, and when a surviving graft was transferred to a normal recipient of the donor *C*57*B*1 strain it was destroyed by a typical homograft response. The results we have outlined may be summarized as providing evidence that, in the *C*57*B*1 or *C*3*H* system, donor cells persist in the homograft for much longer than is now believed, and that if the area is adequately protected, they may regenerate and persist indefinitely despite the recurrence of a homograft reaction. It is much easier to demonstrate this survival if the animals have been pretreated by an injection of the donor type spleen cells, and there are obvious resemblances to the 'enhancement' phenomenon[3,4]. If this is the case, a similar type of homograft survival might be promoted by passive administration of serum from mice which have been hyperimmunized with donor type cells. Accordingly, a group of 16 adult male

C3H mice were grafted with *C57B*1 skin. On the sixth day after grafting, concurrent with the onset of the cellular reaction in the first-set graft response, 10 mice were each injected intraperitoneally with 0·2 ml. of serum obtained from *C3H* mice which were hyperimmunized by the intraperitoneal injection of *C57B*1 spleen cells at weekly intervals over a period of 6 weeks. Thereafter the grafted mice received intraperitoneal injections of 0·2 ml. of the hyperimmune serum on alternate days until the twentieth day after grafting. The remaining 6 control animals were injected with normal *C3H* serum using the same procedure of route, and dosage, with which the test group was treated with hyperimmune serum. The plaster bandages were removed from both groups of mice at 16 days after grafting, and survival of the grafts in the group injected with hyperimmune serum was both macroscopically and microscopically similar to the homograft survival observed in the actively immunized animals described here. The grafts were destroyed in the control group injected with normal *C3H* serum. This is only a preliminary result but it points strongly towards an enhancement effect. Following Billingham, Brent and Medawar[4], we regard this as due to antibody providing an afferent block in the flow of antigenic material (or information) from the implanting donor cells to the immunologically competent lymphoid centres of the host.

The conclusion to be drawn from our experiments may not necessarily be applicable to any other system than the one we have used, but there is equally nothing to show that they are not of general validity. With this reservation we can formulate them as follows:

(1) A proportion of cells of donor origin survive the homograft response and, provided adequate physical protection is given to the graft, many may survive indefinitely. The cells concerned are not, however, sufficient to conserve the donor material as a functioning tissue; they constitute at most a local chimera containing also a proportion of host cells.

(2) The difference between first and second set reactions is essentially in their timing; second set reactions are initiated and reach their acme 4–6 days earlier than primary ones.

(3) Accepting the orthodox interpretation that homograft rejection is mediated by the sequence; movement of antigenic material from the graft to lymphoid tissue; induction and proliferation of appropriate immunologically competent cells; passage of such cells to the graft site; destructive interaction between immunologically competent cells of the host and the donor cells in the graft, we should add a further component to the sequence, namely, production of circulating antibody which, by intervening between foreign antigenic determinant and receptors on immunologically competent cells at either afferent or effector stages, can diminish or annul the immunological rejection of the homograft.

(4) The intensity and completeness of the homograft response is therefore highly dependent on conditions in the system which modify the degree of physical protection of the graft and on the relative timing and intensity of the cellular and humoral aspects of the immune response.

We are indebted to Sir Macfarlane Burnet for his criticism during the course of this work.

A NEMIN ASSAY PROCEDURE

By E. J. WINKLER, SHIMPEI KUYAMA and Prof. DAVID PRAMER

Department of Agricultural Microbiology, Rutgers, The State University, New Brunswick

PRAMER and Stoll[1] provided unequivocal evidence that trap formation by the predacious fungus *Arthrobotrys conoides* is induced by a metabolic product of the nematode *Neoaplectana glaseri* and proposed 'nemin' as the name for the substance or group of substances that cause morphogenesis in nematode-trapping fungi. In order to study the chemical nature of nemin and to proceed with isolation and identification of the compound, it was necessary to have a nemin assay procedure. Therefore, the influence of various factors on growth and trap formation by *A. conoides* was determined, and the results were used as a basis for the nemin assay agar and the method described here.

The fungus used as assay organism was isolated from decomposing leaves and identified as *A. conoides*. It is representative of a group of nematode-trapping fungi in which short lateral branches of the mycelium anastomose with similar branches or with the parent hyphæ to form eventually a three-dimensional network of loops. The hyphæ that comprise the loops are covered with a sticky secretion, and nematodes contacting the network are captured by entanglement in and adhesion to the mycelium[2]. *A. conoides* developed readily on a variety of laboratory media, but stock cultures were maintained by periodic transfer on maizemeal-extract agar. Pure cultures of the fungus produced some traps spontaneously, but they were few in number, and no difficulty was encountered in differentiating between control plates on which traps were produced without provocation and treated plates on which trap formation was induced by nemin.

The assay agar was prepared by dissolving 17 gm. of dehydrated maizemeal-extract agar (Difco Laboratories, Inc.) in 1 l. of *M*/45 Sorenson's phosphate buffer at *p*H 5·8. The liquid was brought to the boil and when the agar dissolved 10 p.p.m. of novobiocin and 20 p.p.m. of bromcresol purple were added. The antibiotic prevented bacterial contamination of assay plates. The buffer maintained the reaction of the assay agar at *p*H 5·5–5·8 and thereby kept spontaneous trap formation to a minimum. Bromcresol purple provided visual evidence of any change in the

Table 1. Nemin Activity of Various Blood Sera and Nematode Extracts

Preparation assayed	Highest dilution causing trap formation	Dry weight of preparation (mgm./ml.)	Nemin (units/mgm.)
(1) Sterile pooled normal serum (Colorado Serum Co., Denver, Colorado)			
Cow	1/1,000	86	11·6
Horse	1/2,000	93	21·5
Pig	1/2,000	87	23·0
Sheep	1/1,000	82	12·2
(2) Bovine serum (Hyland Laboratories, Yonkers, New York)			
Liquid	1/500	58	8·6
Dried*	1/1,000	85	11·8
Ultrafiltrate	1/100	15	6·7
Dialysed	1/100	72	1·4
(3) Water extracts of nematodes			
Panagrellus redivivus	1/1,000	5	200·0
Pig ascarids	1/1,000	27	37·0
(4) Culture broth of *Neoaplectana glaseri*†	1/100–1/1,000	37	2·7–27·0

* Reconstituted in sterile distilled water saturated with CO_2.

† Obtained from Dr. N. R. Stoll, of the Rockefeller Institute, New York.

reaction of the medium caused by material incorporated into the agar for assay or by growth of the fungus. The antibiotic, buffer, and *p*H indicator at the concentrations employed had no influence on growth or trap formation by *A. conoides*. The complete assay agar was sterilized by autoclaving.

Solutions for assay were sterilized by filtration through membranes or sintered glass and diluted in sterile water blanks. One-ml. quantities thereof were added to separate Petri dishes and mixed thoroughly with 9 ml. of the assay agar poured at approximately 45° C. When the agar had solidified, the centre of the surface of each assay plate was inoculated with a plug having a diameter of 4 mm. and cut with a cork borer from those portions of a maizemeal-extract agar plate on which the growth of *A. conoides* was 1–2 days old. All assays were made in triplicate. Results were obtained by microscopic examination (× 100) of the mycelium that developed during 48 hr. storage at 28° C. Observation was neither tedious nor prolonged since the amount of growth made by the assay organism was relatively scant and traps were easily distinguished.

The total solids content of preparations assayed was determined by drying an appropriate quantity at 105° C. for approximately 18 hr. Nemin activity was measured in terms of dilution units/mgm. The nemin unit was the reciprocal of the highest dilution of the preparation that caused the fungus to form traps. If a preparation had a total solids content of 10 mgm. and was active at a dilution of 1 : 1,000 it contained 1,000 dilution units/10 mgm. or 100 units/mgm.

The assay procedure as described was used to determine the nemin activity of various animal sera, aqueous extracts of two nematodes, and culture broths of the nematode *N. glaseri*. It is apparent from the results summarized in Table 1 that water extracts of the free-living nematode *Panagrellus redivivus* had the greatest nemin activity. Sera derived from the cow, horse, pig, and sheep had comparable activity, and dried bovine serum did not differ greatly in nemin content from normal serum. The nemin activity of an ultrafiltrate of bovine serum was similar to whole serum, indicating that the size of the nemin molecule is not too great to pass through 'Cellophane'. This was verified by dialysing bovine serum against distilled water for 2 days. The whole serum had a nemin activity of 8·6 units/mgm., but after dialysis it decreased to 1·4 units/mgm. The loss of nemin from blood serum during dialysis supports the statement of Pramer and Stoll[1] that nemin is not a protein or polysaccharide of high molecular weight.

Since chemical fractionation and isolation work frequently yield small quantities of material, a microassay method was developed and tested. The same assay agar was employed and 10-ml. quantities were added to sterile Petri dishes. When the agar had solidified the plates were inoculated as described above and incubated at 28° C. for 5 days. Holes (5 mm. diameter) were punched from the centre of absorbent paper disks 13 mm. in diameter and 5 disks were placed equally distant from each other around the circumference of the agar surface in each plate. The disks were located such that the mycelium exposed through the centre holes was 1–2 days old. The preparations assayed were diluted serially in water and 0·1 ml. aliquots of the solutions added directly to the fungus mycelium visible through the holes in the centre of the absorbent disks. All tests were made in triplicate and the plates returned to the incubator for 36 hr. The treated areas were then examined microscopically for traps and nemin activity measured as dilution units/mgm. The micromethod was found suitable for locating nemin on paper strip chromatograms. For this purpose the strips were cut into 2-cm. lengths and these were substituted for the absorbent disks.

The micromethod requires 0·1 rather than 1·0 ml. of solution for assay. Moreover, 5 determinations instead of 1 are made per plate and results are read after 36 rather than 48 hr. Repeated tests have shown that both assay procedures yield comparable results. The nature, quantity of material, and time available for assay dictate which of the two methods is the more suitable. A dilution assay such as that developed for the estimation of nemin is limited in its sensitivity since measurements can be made only between concentrations of the dilution series tested. Precision can be increased by using more narrow increments in a dilution series, but this necessitates an increased expenditure of time and effort. In the nemin assay the preparations to be tested were sterilized. Although this is not a requirement of the micromethod, results are more reproducible and clearly defined when aseptic technique is employed. In spite of these disadvantages which are inherent in all serial dilution assays the procedure remains a useful and important means of measuring the activity of biologically active compounds[3]. Repeated tests have shown that the results obtained with the nemin assay are reliable and reproducible and the method as developed is suitable for the control of fractionation studies for the chemical isolation and identification of nemin. For this purpose pig ascarids are being used. These worms are numerous, individually large, and obtainable in quantity from slaughter houses. The results listed in Table 1 show that water extracts of pig ascarids have greater nemin activity than animal sera and culture broths of *N. glaseri*.

This investigation was supported in part by National Science Foundation research grants *G*5949 and *G*9749 and the Rockefeller Foundation.

RADIOPHYSICS

Group and Phase Velocities of a Travelling Disturbance in the *F* Region of the Ionosphere

A PUZZLING feature of the reported association[1] between travelling disturbances in the *F* region and the occurrence of sporadic *E* is that travelling disturbances move with a velocity of about 10 km./min. (ref. 2) whereas sporadic *E* patches have only about half this velocity[3]. However, the travelling disturbance velocity was measured using widely spaced stations (~ 1,000 km.) whereas that of the sporadic *E* patches was found using relatively close stations (~30 km.). Therefore whereas it is the group velocity of the travelling disturbances which has been measured, the sporadic *E* patches may be associated with a particular phase of the isoionic contours in the travelling disturbance and may thus appear to move with the phase velocity of the travelling disturbances.

To test this hypothesis, three methods have been used for measuring directly the phase velocity of a travelling disturbance, making use of existing records. The ionograms taken at one station have been reduced to give isoionic curves plotted against time. These curves are then used in the following ways:

(1) The radius of curvature of the isoionic contours in space may be estimated from the observed splitting of the echo. For example, when the second echo is split, but the first is not, the radius of curvature is between once and twice the height of the contour. When the radius of curvature at any time is known, the phase velocity may be estimated.

(2) The second echo virtual path is often less than twice the virtual path of the first echo, because of the different paths followed. If the isoionic contours are assumed to be concentric circles over short distances, it is possible to calculate the difference in terms of known quantities and the phase velocity.

(3) The wave-fronts of travelling disturbances are believed to be approximately along the Earth's magnetic field[3,4]. If this is assumed to be correct, a further estimate of phase velocity may be made using the isoionic curves.

One set of two-minute records taken at Brisbane has been found suitable for analysis. The group velocity of the disturbance was found from ionograms at this and other stations to be 10 km./min. All three methods gave a phase velocity between 4 and 6 km./min., confirming the hypothesis.

The difference in group and phase velocities may also explain the short apparent life-time (~30 min.) of phase-path irregularities[5] and the long life-time of disturbances on ionograms at spaced stations (~5 hr.). The form of the phase path irregularities changes rapidly due to the large dispersion.

'Satellite' traces on ionograms are due to sloping isoionic contours which are observed to move with a velocity of ~4 km./min. (ref. 6). Because of the method used for measuring it, this velocity is evidently the phase velocity. Thus the one obstacle to the identification of the cause of satellite traces as travelling disturbances, that is, their different velocities, is removed.

The travelling disturbances discussed here are those which cause gross distortions of ionogram records. Small disturbances on $h' : t$ records have been shown to move with speeds of nearly the same magnitude[7], but differing in direction by about 20°. This may be due to the influence of the phase velocity, which may have an east–west component not appearing in the group velocity which is nearly due north.

The reported dispersion does not agree with that given by Hines[8] for internal gravity waves which he regards as the cause of travelling disturbances.

Further details of the experimental method will be presented elsewhere.

OCEANOGRAPHY

Evidence of an Eastward Equatorial Undercurrent in the Atlantic from Measurements of Current Shear

RECENTLY there has been speculation as to the existence of an equatorial countercurrent in the Atlantic Ocean similar to the Cromwell Current[1,2] in the Pacific. G. Neumann[3] has cited evidence for such a current from early observations (1911) of anomalous drift currents and from a re-analysis of dynamic heights from oceanographical data along the equator. In the first two weeks of March, 1961, during an extensive bathymetry survey of the mid-Atlantic Ridge along the equator, I was able to make a number of measurements of horizontal current shear in the upper 100 m. surface water. The shears obtained at different points over an area extending from 19° W. to 10° W. longitude and from the equator to 3° S. latitude do indicate the presence of an eastward flowing equatorial undercurrent. The measurements were made from the R.V. *Chain* during the first part of a three-month cruise to study oceanographical problems associated with the Romanche Trench and the equatorial mid-Atlantic Ridge.

The current shear was measured by a method suggested to me by W. S. Richardson of this Institution. Two pitotmeters were mounted at the top and bottom, respectively, of the 600-ft. towed chain which carried thermistor elements for the continuous temperature profiling system[4]. When the ship was under

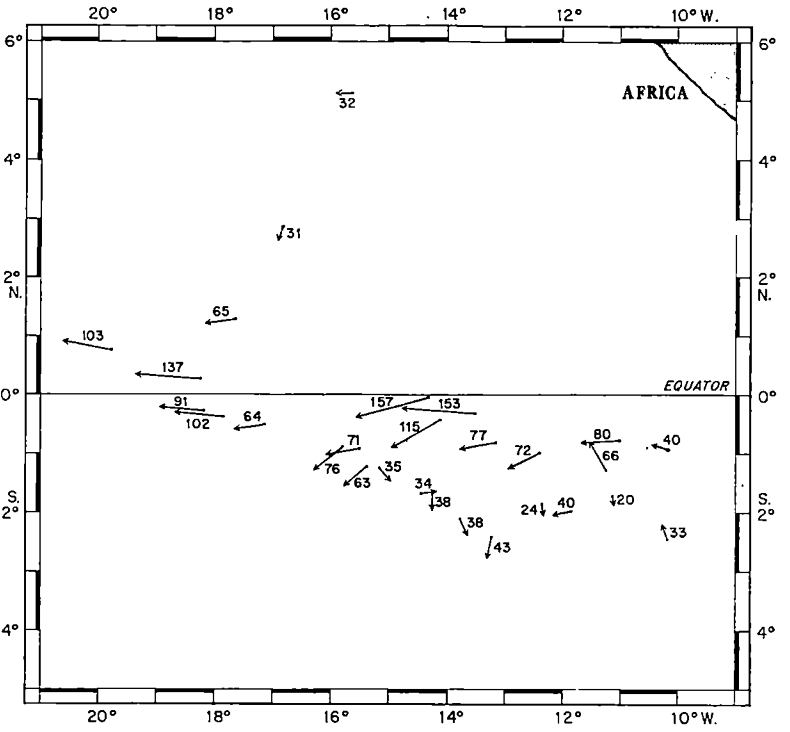

Fig. 1. Horizontal current shear [$\vec{V}$ (15 m.) − $\vec{V}$ (105 m.)] measured near the equator during March 4–21, 1961 (shear magnitude in cm./sec. indicated beside each vector)

way at a normal speed of 11 knots the shallow pitotmeter was at a depth of 15 m. and the deep pitotmeter at a depth of 105 m. The water speed past each pitotmeter was determined electrically from a differential pressure transducer driven by the pitot. By manoeuvring the ship at constant speed (11 knots) around a box course I could measure the vector difference between the current velocity at the pitotmeter and the drift velocity (wind drift and surface current) of the ship at the surface. By subtracting the result of one pitotmeter from that of the other I could determine the vector difference or shear between the current velocities at the two pitotmeters.

The preliminary results of shear measurements are shown on the chart in the accompanying Fig. 1. Each vector represents a measurement and gives the magnitude and direction of the difference: $\left[\vec{V}\text{ (15 m.)}-\vec{V}\text{ (105 m.)}\right]$, where $\vec{V}$ (15 m.) is the current velocity at a depth of 15 m. and $\vec{V}$ (105 m.) is the current velocity at 105 m. The magnitude of the shear in cm./sec. is indicated beside each vector. Clearly apparent in Fig. 1 is the unusually strong westerly shear of the 15-m. water over the 105-m. water along the equator. This shear was as high as 150 cm./sec. in two places. The shears shown give no information, of course, about absolute current velocities. However, determinations of the set of the ship while under way and while drifting indicate a current velocity at the surface of 40–60 cm./sec. to the westward at the equator. Because the current at 15 m. was about the same as that at the surface it is clear from the shears shown that the undercurrent at the 105-m.-level is toward the east along the equator and at some points as high as 100 cm./sec. The presence of this undercurrent was indicated very clearly during the lowering of a plankton net prior to a tow. When the net reached a depth of about 50 m. the wire angle changed drastically and stood out from the ship towards the east.

The shears shown in Fig. 1 indicate that the southern boundary of the undercurrent in these longitudes lies somewhere between 1° and 2° south latitude. The few measurements north of the equator show very little concerning the northern boundary of the undercurrent, but suggest that the current is more or less symmetrical about the equator. The thermal structure of the water, which was recorded continuously throughout the survey to a depth of about 110 m., underwent an interesting transition whenever the ship crossed the boundary of the current. South of the current most of the total drop in temperature from 28° C. at the surface to 15° C. at 110 m. was concentrated within a very strong negative gradient at a depth of about 50 m. This gradient is the well-known equatorial discontinuity layer. Along the equator, however, the drop in temperature was distributed evenly from the surface to 110 m. with an approximately constant negative gradient.

This work was carried out under contract with the Office of Naval Research (*Nonr*-1367).

Measurements of the undercurrent are continuing aboard the R.V. *Chain* in this area at the time of writing. Detailed measurements of the undercurrents velocity profile are being made using current meters and current drogues by C. Parker.

GEOLOGY

Ultrabasic Liquids

THERE is a considerable body of geological evidence suggesting that, in a submarine environment, extrusion of silicate liquids with a composition comparable to peridotite occurs. Later, this material is hydrated to form serpentine. In part, this evidence comes from repeated association of serpentines with marine sediments such as greywackes and cherts, and repeated association with volcanics including pillow lavas. Further, the ultramafics of this environment show features to be expected from rocks which have flowed. An excellent description of such a situation is provided by Bailey and McCallien[1]. Hess[2] has summarized some of the data from field evidence suggesting that many ultrabasic rocks were formed by intrusion of liquids. But laboratory investigation has consistently heaped difficulties on an extrusive explanation of such rocks. Known surface lava temperatures do not exceed 1,200° C. while the melting temperatures of the anhydrous equivalents of serpentine are of the order of 1,700° C. Clearly there are difficulties in moving such materials to the surface of the Earth, or even in forming liquids at reasonable depths in the crust. The following statement from Hess[2] bears repeating : "For most of this century a magnificent argument has gone on between field geologists who have worked on the peridotites of alpine mountains and laboratory investigators of their chemistry (particularly Bowen). The former stoutly maintains that the evidence indicates that they were intruded in a fluid state, as magmas ; and the latter equally forcefully has proved to his satisfaction that such magmas are not possible. . . . At the other extreme we find Bailey and McCallien suggesting that the serpentines of Turkey are submarine lava flows."

Recent work has shown that submarine volcanic activity is widespread but the consequences of this have received insufficient attention. Under moderate pressures of water, the melting points of rocks and minerals are normally depressed several hundred degrees. When a lava is extruded at the surface, it cannot contain volatiles at pressures much in excess of atmospheric pressure. When the same material is extruded in a submarine environment, volatiles can be retained at pressures corresponding to the water pressure of the given depth. It follows that submarine lavas will occur at much lower temperatures than their surface equivalents. If silicate liquids corresponding to compositions with high melting points are to be expected as extrusives, the most likely environment will be that of the deep oceans.

With these considerations in mind, a series of preliminary experiments on the melting points of serpentine compositions have been conducted under water pressures of 500–1,000 atm., corresponding to the deeper parts of the oceans. The material chosen was a typical serpentine from a typical 'flow' environment in New Zealand. Hydrothermal treatment indicated that above 500° C., the serpentine was replaced by talc and forsterite. At higher temperatures, forsterite, enstatite and minor chromite were dominant. Between 900–1,200° C., pyroxene and olivine were fine-grained, but near 1,300° C. the first suggestions of melting were indicated. By 1,400° C. it was clear that most of the material was liquid during the experiment. Residual olivine was coarse-grained; glass was present together with masses of feathery growths of olivine or pyroxene. This latter growth habit is typical of that in greatly supersaturated environments and probably took place during quenching, a matter of a few seconds. Samples also suggested that considerable flow of material had occurred.

It thus appears that serpentine lava could flow at temperatures of about 100° C. above observed surface lava temperatures, in a submarine environment. In our opinion, such temperatures cannot be considered beyond the range of geological possibility. At greater depths, intrusion of partially melted ultramafic materials should be possible at even lower temperatures. Our quenching results also indicate that well-quenched margins should be rare.

It has been noted frequently that ultrabasic rocks seldom show thermal effects at their contacts, which might be anticipated from their melting temperatures (for a summary, see Turner and Verhoogen[3]). In the case of submarine flows, no contact metamorphism would be anticipated. But even in deeper intrusions it must be noted that the demand for water imposed by the serpentine reaction in chilled marginal phases may cause flow of water into the cooling magma and an abnormally low heating effect at contacts. This situation is in direct opposition to that with granitic rocks where internal water requirements are small, and transfer of water out from the magma may heat contact rocks.

Preliminary Age-Determinations in the Lizard Area

A PETROLOGICAL re-examination of the Lizard area by one of us (D. H. G.) has led to an attempt to date the igneous and metamorphic assemblages using the potassium–argon method.

Four muscovite samples from the Old Lizard Head series and two samples of biotite from the Kennack gneiss have been measured, using the total volume technique. Determinations of potassium oxide were made using a flame photometer. Results are shown in Table 1. Overall errors are estimated at ± 4 per cent. On geological evidence, the relevant sequence of events in the Lizard is as follows :

Oldest: (1) Regional metamorphism of (*a*) Old Lizard Head series, (*b*) Landewednack hornblende schists, accompanied by the intrusion of the Lizard peridotite. (2) Localized intrusion of gabbro. (3) Intrusion of a basic dyke swarm and related sills, intruded in a stress field approximately at right angles to that operating during the regional metamorphism. (4) Minor intrusions of Kennack granite and injection gneiss. (5) Thrusting of the Lizard block over the Palæozoic sequence to the north.

The age of event (5) is probably Upper Devonian or Lower Carboniferous, but events (1) have been assigned to ages from Archaean[1] to Upper Devonian or Lower Carboniferous[2].

Ages given in Table 1 are not consistent with the established sequence of geological events. Retrograde effects in the biotite–hornblende injection gneiss of the Kennack gneiss are absent or restricted to slight sericitization of feldspar. The specimens of Old Lizard Head series are muscovite–chlorite schists in which the chlorite probably has replaced biotite, and in which cordierite has altered to secondary products. Plagioclase is fresh or shows slight sericitization. Muscovite itself appears quite fresh.

The interpretation placed on these results is that the date given for the Kennack gneiss is a true one, indicating a Caledonian[3] age for the acid intrusion. That obtained for the Old Lizard Head series probably reflects loss of argon caused by slight retro-

CRYSTALLOGRAPHY

Epitaxial Growth of Crystals on One-Degree Orientated Substrates

During the oxidation of one-degree orientated metals, an unexpected variation in the dispositions of oxide crystallites was observed which appears to be similar to epitaxial growth[1] of crystals on single crystal substrate. In this process, the growing crystals (overgrowths) aligned themselves in a certain manner depending on the arrangement of atoms or ions of the substrate and more correctly on the potential energy configuration at or near the surface layers. Consequently a definite orientation relationship is established between their crystal axes, and the overgrowths are said to develop a two-degree orientation such that two axes of theirs are parallel to two of the substrate. This is more often expressed by a plane and axis of each. Single crystal substrates thus greatly influence the orientation of the overgrowths at least in the initial stage of their growth[2]. On different faces of the substrate, the deposit orientation would normally be different, provided the growth condition is not too drastic or temperature not too high. The same orientation may, however, be induced on different faces of the substrate, but is again determined by the substrate structure. Numerous illustrations of such epitaxial growth of crystals are cited in the literature (see Pashley[3]).

On polycrystalline and amorphous substrates, this type of orientated overgrowths is not observed, simply because there is no regular order in the disposition of crystallites of the substrates in the former and no regular periodicity in the atomic arrangement in the latter. In one-degree orientated substrates, however, there is some partial order in distribution of crystallites in the sense that they have a common and parallel axial direction (or plane), known as orientation axis (or plane); but otherwise they are all randomly disposed. No result is yet published which suggests the influence of such substrate on the growing crystals. In view of my observation mentioned earlier, orientated metal substrates were oxidized slowly in air and the nature of the oxide crystals studied by electron diffraction.

Nickel electro-deposits of {100}, {110}, {210} and {10$\bar{1}$0} + {211} orientations (one-degree) and cobalt of {110} were prepared by electro-deposition[4]. These were then heated in air in an electric furnace to a temperature of about 320° C. for about an hour and the surface layers examined by electron diffraction both before and after oxidation in the usual way[3,4].

Table 1

Substrate orientation (1-*d*)*	Oxide orientation (1-*d*)*
Ni {100}	NiO {100}
Ni {110}	NiO {110}
Ni {210}	NiO {210}
Ni (10$\bar{1}$0) + {211}	NiO {111}
Ni {Poly}	NiO
Co {110}	Co_3O_4
Co {110} †	CoO {110}

* 1-*d*: one-degree orientation.
† At about 10^{-2} mm. mercury pressure of air.

Nickel metal was oxidized to nickel monoxide (NiO) only, whereas cobalt to cobalto-cobaltic oxide (CO_3O_4) in air, but to cobaltous oxide (CoO) only at low pressure ($\simeq 10^{-2}$ mm. mercury) of air. The surface layers on nickel substrates consisted not only of orientated polycrystalline monoxide but also of unreacted metal. Nickel monoxide (NiO) crystallites developed different orientations depending on the nature of initial substrate orientation (Table 1). But under the same conditions, polycrystalline nickel was oxidized to unorientated nickel monoxide. On further heating, however, entire surface layers, whether of orientated or unorientated nickel, consisted of polycrystalline nickel monoxide only. Further oxidation would lead to nickel monoxide, having preferred orientation determined entirely by the oxidation conditions similar to cuprous and cupric oxides on copper[5]. For better orientation the oxidation should be carried out at mild conditions. On cobalt {110} surface under milder conditions of oxidation at low pressure, again {110} orientated cobaltous oxide was observed.

These results clearly show that the overgrowth orientations can also be influenced considerably by substrates orientated one degree, at least in the initial stage of growths, and the process closely resembles the epitaxial growth on single crystals.

GEOCHEMISTRY

Fossil Chlorins in a Triassic Sediment

Spectroscopic evidence for the presence of green chlorophyll-derivatives in ancient sediments and crude oils has been reported by Treibs[1] and by Blumer[2]. We have now succeeded in isolating and characterizing the green pigments responsible for the absorption band at about 640 mμ in the extracts of the porphyrin-rich Triassic oil-shale from Serpiano (Switzerland) (Fig. 1*A*). The pigments are isolated by first removing from the extracts the asphaltenes by iso-octane precipitation and extracting the ether solution of the pigment-concentrate with 6 *N* hydrochloric acid. Subsequent partitioning between ether and hydrochloric acid of increasing concentration removes the stronger bases deoxophylleryrthroetioporphyrin (DPEP) and meso-etioporphyrin (MEP). The final purification of the green pigment is then accomplished by repetitive chromatography over partially deactivated alumina (Brockman III). The spectrum of the pure pigment (Fig. 1*B*) is characteristic of the chlorin (dihydroporphin) configuration, and the partial resolution of the band at 490 mμ in addition to the presence of a small band at 612 mμ is indicative of a meso-chlorin, a chlorophyll-derivative in which the vinyl-group in the 2-position has been hydrogenated to an ethyl-group[3]. The high chromatographic mobility of this pigment on alumina and on paper (R_F = 0·75 on Whatman No. 3 paper, carbon tetrachloride–iso-octane developer, 7 : 3, see ref. 4) eliminates the possibility of the presence of acid-, ester- and other polar groups like —COH, —CO, —OH.

The pigment, which is thus characterized as a meso-etiochlorin, can be converted to the corresponding porphin by dehydrogenation with excess chloranil in boiling xylene. The reaction product (Fig. 1*C*) exhibits a typical porphyrin spectrum, intermediate between those of DPEP and MEP and identical with that of the DPEP/MEP-mixture present as uncomplexed pigments in the same sediment. This dehydrogenation product can be resolved by chromatography over alumina into fractions with the etio-spectrum of MEP and phyllo-spectrum of DPEP. Paper chromatography of these fractions confirms the spectroscopic evidence, the R_F-values agreeing within ±0·01 unit with those for pure DPEP and MEP.

For additional structural confirmation, the unknown dihydroderivative of DPEP was synthesized by hydrogenating with Raney-nickel a DPEP concentrate isolated from the oil shale. The spectrum of the hydrogenation product is identical to that of the fossil chlorin. A small difference in the R_F-values (0·68 for the synthetic compound, compared with 0·75 for the natural chlorin) is explained by the presence of a larger fraction of the more rapidly moving dihydro-MEP in the natural pigment.

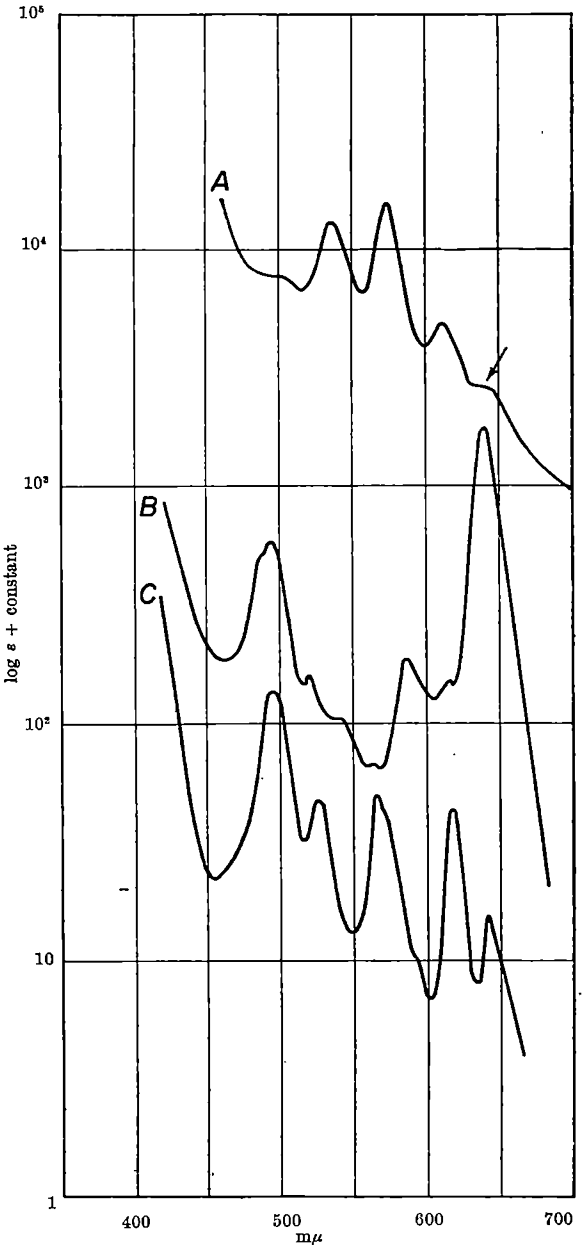

Fig. 1. Spectra. *A*, Benzene–methanol extract of Serpiano oil-shale; *B*, natural dihydro-DPEP containing some dihydro-MEP; *C*, porphyrin mixture obtained by dehydrogenation; the small peak at 641 mμ is a trace of residual chlorin

Thus, the fossil chlorin is characterized as a mixture of dihydro-DPEP (deoxo-meso-etio-pyro-pheophorbide *a*) with some dihydro-MEP (etiochlorin III). The etiochlorin must have been formed by intensive reduction from hæmin, protoporphyrin, mesoporphyrin and meso-etioporphyrin being intermediates. The chlorin structure of dihydro-DPEP is also more likely to be of secondary than of primary origin. The vinyl-group of the chlorophyll-pigments disappears early in geological history, probably by isomerization of the vinyl-chlorins to meso-porphyrins.

Any meso-chlorins that might be formed at this stage would be re-oxidized to meso-porphyrins because of their extremely low redox-potential. Only much later, after complete reduction of all carbonyl-groups, can the porphyrin-system be partially reduced with formation of the fossil chlorins.

A more detailed report of this work is being prepared for publication elsewhere. This investigation has been supported by a research contract with the United States Office of Naval Research (Contract *NONR*-2196 (00)) and the grant of a summer fellowship to one of us (G. O.).

PHYSICS

Iron-55 from Nuclear Detonations

It is well known that the large numbers of neutrons released during nuclear bomb detonations (~0·5 kgm. neutrons per megaton explosion)[1] can induce high levels of radioactivities in the hardware and associated structures of the apparatus. Of particular interest is iron-55, an X-ray emitter with a half-life of 2·6 years, formed by (n, $2n$) and (n, γ) reactions on iron-56 and iron-54, respectively.

The site of high specific activity of iron-55 should be in the marine environment where stable iron exists in very low concentrations (~10 μgm./l. sea water). Radioactive iron falling on continental surfaces will be diluted readily in the large amounts of iron already existing there.

We thought it desirable to ascertain the present content of iron-55 in the oceans. Although this can be accomplished by measuring the vertical depth profiles of iron-55 contents at a number of marine locations, a more expeditious approach is the isolation of the iron activity from organisms that concentrate this element from the oceanic environment. The tuna fish which inhabit both the deep and shallow waters of the seas seemed especially suitable for this purpose since they may be considered to sample rather large areas because of their extensive migratory habits.

Ten kilograms of livers and hearts of tuna fish collected from the Pacific Ocean were digested with nitric and perchloric acids. The residue was dissolved in 8 *N* hydrochloric acid and the iron extracted with isopropyl ether. Further purification was achieved by fixing the iron on an anion exchange resin. The amount of elemental iron recovered was 2·5 gm.

The sample was assayed in a proportional counter shielded by 8 in. of iron and with an appropriate anti-coincidence arrangement. The purity of the activity was determined by comparing the spectrum of emitted X-rays with that of a standard iron-55 source. The specific activity of the samples, in February 1961, was found to be 82,000 d.p.m./gm. of iron. This value may be compared with those of other artificial and natural isotopes in the marine environment: strontium-90, 10 d.p.m./gm. strontium; cæsium-137, 500,000 d.p.m./gm. cæsium; and uranium-238, 700,000 d.p.m./gm. uranium. Since iron is generally the most abundant heavy metal in the marine biosphere, the activity-level of iron-55 is probably the highest. It should be noted that it is not great enough to constitute a health hazard.

An approximation of the iron-55 inventory in the Pacific may be obtained from the observed average specific activity of the oceanic iron. Assuming a concentration of 10^{-5} gm. iron/l. of sea water and an average oceanic depth of 4,000 m. (that is, 400 l./cm.^{2}), the iron-55 inventory in the Pacific should be of the order of $82,000 \times 10^{-5} \times 400$ or 330 d.p.m./cm.^{2} of oceanic area. Most of this activity probably still resides in the upper water inasmuch as the marine biosphere tends to promote an accumulation of iron in the oceanic mixed layer[2].

An attempt was made to find out whether any significant fraction of the iron-55 activity had already settled to the sea floor. The upper 1 cm. of sediment layer was taken from two cores of total cross-sectional area of 40 cm.^{2}, raised in the Pacific (28° 58′ N.; 117° 28′ W.; 3,600 m. depth) in April 1961. The sample was leached with 6 *N* hydrochloric acid and the iron in solution was extracted and purified as described above. The iron-55 activity in the entire sample was very small ($\leq$ 3 d.p.m.), implying that only an insignificant fraction of the activity had settled to the ocean bottom during the past few years.

In order to obtain a measure of atmospheric fall-out to the oceans, rain from San Diego was assayed for iron-55 activity. It yielded a value of 0·8 d.p.m./l. in February 1961. This indicates that the present contribution of atmospheric fall-out is small compared with the total inventory in the ocean. One metre of rainfall introduces only about 0·08 d.p.m. of iron-55 annually per cm.^{2} of oceanic area.

Quenching of Cation Vacancies in Doped Crystals of Sodium Chloride

As is well known, the thermodynamic defects developed by alkali halide crystals at high temperatures are predominantly of the Schottky type. The number of cation and anion vacancies in equilibrium with the crystal, at temperatures near the melting point, for example, may be as large as 10^{-4} of the total number of atoms. Attempts have, therefore, been made to quench these vacancies by very rapid cooling from these high temperatures, but without success, judging from the very similar values obtained for the electrical conductivities of the quenched and the annealed specimens[1]. (From the melt, however, some of the defects can be quenched.) This, however, is not surprising, since the relaxation times corresponding to the migration of vacancies, leading either to formation of pairs or to their exit from the crystal, remain small, even at temperatures several hundred degrees below the melting point.

Cation vacancies can also be introduced, as is well known, by suitably doping the crystal. For example, by doping sodium chloride with cadmium chloride, it is easy to see that at sufficiently high temperatures the number of cation vacancies produced by the doping will be just the number of Cd^{++} ions held in solution. We find experimentally that such vacancies, unlike the natural Schottky ones, can be quenched effectively. There are many advantages, as we shall see presently, in working with such quenched crystals, since the number of cation holes is then known definitely, and can be made fairly large. It may be mentioned incidentally that though extensive work has been done on annealed specimens of doped crystals, by Maurer *et al.*[1], quenched specimens do not seem to have been studied.

In the present experiments large clear crystals of sodium chloride containing known molar concentrations c of cadmium chloride, ranging from 2×10^{-5} to 7×10^{-4}, were grown from the melt in the usual manner. They were annealed at about 1,050° K., which is 27° below the melting point of the pure crystal, and then suddenly dropped into liquid nitrogen and thus allowed to cool rapidly. Although many of the crystals developed cracks, it was possible to obtain specimens free from cracks that were large enough for electrical conductivity measurements. Fig. 1 gives a plot of the conductivity σ of the quenched crystals at four different temperatures up to about 720° K. These temperatures were low enough to leave the quenching undisturbed. The observed small residual conductivity of the 'pure' crystal at these temperatures was corrected for. It corresponded to a doping concentration of cadmium chloride of about $4 \cdot 6 \times 10^{-6}$. It will be seen that they plot into straight lines, naturally passing through the origin. In Fig. 2 are plotted the values of $\log(\sigma T/c)$ against $1/T$, from which it will be seen that the values for all the concentrations plot on the same straight line. One may draw the following conclusions from this: (1) that even at the highest temperature of measurement, namely, 720° K., the number of cation vacancies produced by quenching remains undisturbed, and is therefore independent of the temperature of measurement; (2) that this number is proportional to the concentration c up to the highest concentration studied, namely, 7×10^{-4}, and must, therefore, be the number obtaining at the high temperature, and hence the same as the number of Cd^{++} ions doped into the lattice; in other words, while all the cation vacancies produced by the dope at 1,050° K. have been frozen intact, almost none of the natural cation vacancies of the Schottky type, the number of which also is considerable at this high temperature, has been frozen; (3) since the relaxation time corresponding to the migration of a cation hole to the neighbourhood of Cd^{++} is small, that the observed proportionality of the quenched number of holes to the concentration of cadmium points to a low value for the energy of pairing of a cation vacancy with a Cd^{++} ion.

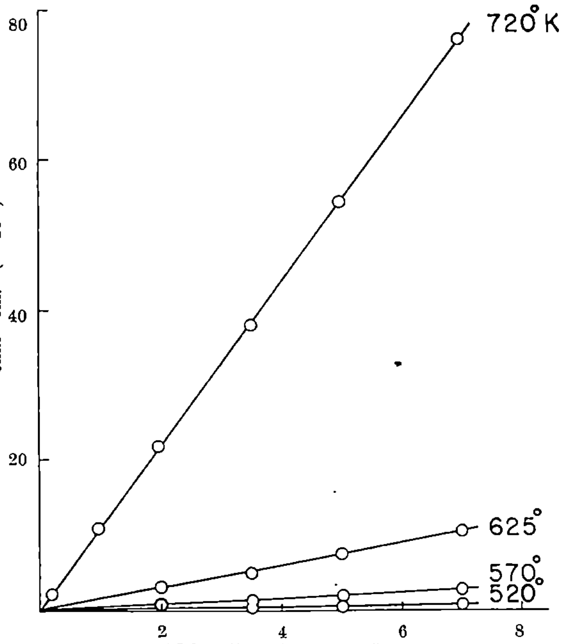

Fig. 1

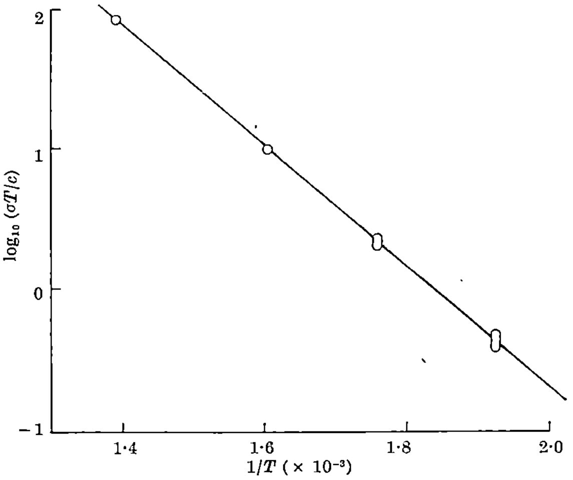

Fig. 2

Using the well-known expression for the conductivity, namely, $\sigma = ne\mu$, where $\mu = (eva^2/kT)$, $\exp(-U/kT)$ is the mobility of the cation vacancy, and $U = U_0 - \alpha T$ is the activation energy corresponding to the mobility, one obtains from the slope of the straight line in Fig. 2, $U_0 = 0 \cdot 85$ eV., and from the intercept on the y-axis the value $\exp(\alpha/k) = 460$, which is large, but of the right order of magnitude. This value of α would correspond to a temperature coefficient of U given by $-(1/U_0)\mathrm{d}U/\mathrm{d}T = 6 \times 10^{-4}$.

On annealing the crystal by very slow cooling from high temperatures, by about 15° in a day, the effective number of cation holes drops. This cannot be attributed to the formation of pairs of cation holes with Cd^{++} ions, since this process has the same small relaxation time as for the pairing of the Schottky vacancies, and would therefore have occurred even without the annealing, if the energy of combination had been large enough.

One is forced to the conclusion that the reduction in the number of cation holes by annealing must be due to the elimination of these holes, and of the same number of Cd^{++} ions, by a much slower process, probably by precipitation as cadmium chloride. This accounts for the possibility of quenching these cation vacancies, but not the Schottky vacancies. Such precipitation may be merely a consequence of the decrease in the solubility of cadmium chloride with decrease of temperature. The development of turbidity by these crystals on annealing lends support to such a precipitation.

Ultrasonic Velocity in Aqueous Solutions of Some Electrolytes

While carrying out investigations in a number of aqueous solutions of electrolytes, we have observed the interesting feature of a decrease of ultrasonic velocity with increase of concentration in the case of aqueous solutions of calcium iodide, zinc bromide, silver nitrate and cerous acetate, contrary to the normal type of behaviour exhibited in general by electrolytes. Velocity measurements in the above solutions of electrolytes at 30° C. were carried out using a fixed-path, variable frequency interferometer[1], at a frequency of 1·5 Mc./sec. The accuracy of the measurements is ± 1 m./sec. The variation of density with concentration in all the above cases is found to be linear.

The variation of ultrasonic velocity with concentration is shown in Fig. 1. In all the electrolytes investigated, zinc bromide, calcium iodide and silver nitrate exhibit a decrease in velocity of 88, 43 and 40 m./sec., respectively, for a concentration of 3 moles/litre. In spite of the peculiar behaviour in the variation of velocity with concentration, it is found that the adiabatic compressibility shows a regular decrease with increase of concentration in all these electrolytes. All other properties, like molar sound velocity and apparent molal compressibility, also showed a regular linear variation with concentration except in the case of cerous acetate, for which the variation of apparent molal compressibility with concentration is irregular.

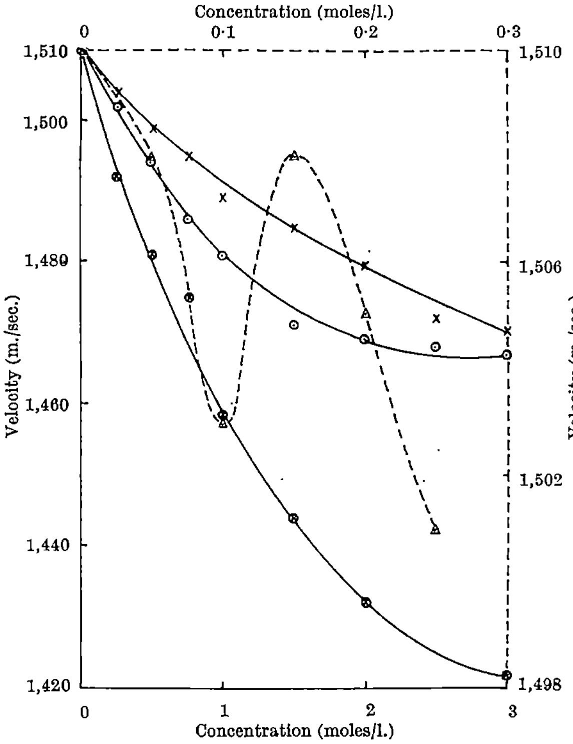

Fig. 1. Variation of ultrasonic velocity with concentration in aqueous solutions of electrolytes. ⊙, Calcium iodide; ×, silver nitrate; ⊗, zinc bromide; △, cerous acetate

It has been reported by earlier investigators[2-4] that electrolytes with heavy radicals or those having complex ions exhibit a decrease in velocity with increase in concentration. The decrease of ultrasonic velocity in the case of zinc bromide can be explained as due to the formation of complex ions, and that in calcium iodide as due to the heavy acid radical. But in the case of silver nitrate which does not form any complexes in aqueous solutions this result is unusual as similar salts like barium nitrate[5], with heavier metallic radicals, show an increase of velocity with concentration. In the case of cerous acetate the irregular variation of velocity with concentration is interesting.

RADIATION CHEMISTRY

Photochemical Production of Semiconducting High Polymers

Polymers may be rendered semiconducting by heating to form graphitic structures[1]. Such non-specific treatment results in a drastic deterioration of physical properties of the polymer and a change in form of the samples. We have found that ultra-violet light irradiation of chlorinated high polymers transforms them into semiconductors. This treatment has advantages over the pyrolysis method in that: (*a*) by selective choice of ultra-violet wave-lengths specific chemical reactions are produced; (*b*) the reactions may be confined to specified areas. In fact, we have found that at the border of irradiated regions unique *p–n* junctions are produced.

In our experiments we irradiated films about 12µ thick of a commercially available saran which is a copolymer of vinylidene chloride (85 per cent) and vinyl chloride (15 per cent). All additives present were removed by soaking in acetone and then in ethanol so that no carbonyl groups are observed in the infra-red spectrum. For exclusively far ultra-violet irradiation we employed a 15-W. mercury resonance lamp (General Electrical Germicidal) which produces mainly 254 mµ. For near ultra-violet irradiation we used a 100-W. intermediate pressure lamp (Hanovia *SH*) in conjunction with a Corning 9–53 glass filter which removes all wave-lengths below 300 mµ, and for mixed irradiation this lamp was used without a filter.

Irradiation with far ultra-violet produces materials the spectra of which are given in Fig. 1. After subtracting out the background (curve *A*) the curves exhibit a broad maximum at about 285 mµ. The shape of the curve and the position of the maximum are maintained

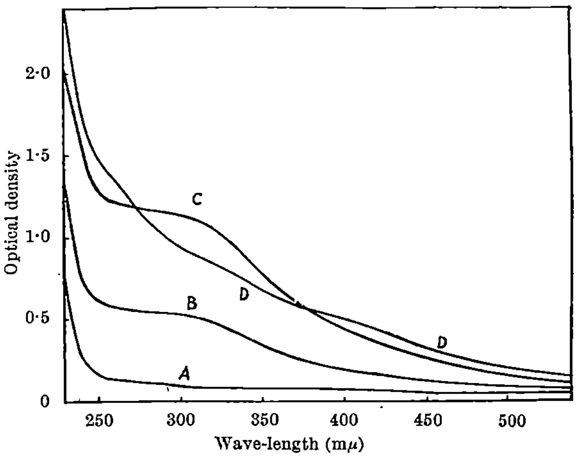

Fig. 1. Spectra of irradiated saran. *A*, original; *B*, far ultra-violet irradiated 2 hr.; *C*, far ultra-violet irradiated 4 hr.; *D*, sample *C* irradiated with near ultra-violet 1 hr.

as the irradiation is continued. This shows that distinct species are being produced in greater and greater amounts, but their relative concentrations are fixed. This is contrary to the generally adopted view[2] that increased irradiation of chlorinated polymers results in progressively more long-chain conjugation. The maximum at 285 mμ suggests the presence of a chlorinated compound containing three conjugated double bonds. It is possible that this is a ring compound formed between neighbouring chains. In fact, irradiation of saran by far ultra-violet is accompanied by cross-linking just as is the case with other high polymers[3], and the gel fraction (determined by insolubility in dioxane) is proportional to time of irradiation. Heating at 100° C. for a few hours of previously irradiated sample results in both an increase in absorption and an increase in cross-linking, both effects being enhanced the greater was the time of previous irradiation. Unirradiated samples heated in this manner show no cross-linking and no change in absorption. The absorption maximum at 285 mμ is proportional to the time of irradiation even up to large optical densities. It is evident that the sensitizer for this reaction is present in large concentration and since the original sample has a low absorption at 254 mμ this strongly suggests that the carbon–chlorine bond is the site of the photochemical reaction.

The tail of the absorption spectrum extends into the visible region and accounts for the brownish appearance of the irradiated film. Irradiated film exhibits a yellow-orange fluorescence (phosphorescence at liquid nitrogen temperature) under excitation with light up to about 400 mμ. Near ultra-violet light irradiation results in destruction of the species associated with the 285 mμ maximum by a photoxidation reaction and causes an increase in absorption below 240 mμ and above 390 mμ (curve *D*). Samples not previously irradiated with far ultra-violet are unaffected by near ultra-violet irradiation.

Far ultra-violet irradiation produces stable free radicals as shown by electron spin resonance spectra, and the spectral curves are symmetrical and structureless. For sample *B* of Fig. 1 there are 10^{15} spins/gm. The intensity of the signal is proportional to the time of irradiation and heating at 100° C. destroys the signal. Samples first irradiated with far ultra-violet and then with near ultra-violet show an unsymmetrical magnetic resonance absorption band. The free-radical species produced by far ultra-violet is preserved and the next species produced by near ultra-violet is superposed on the spectrum. Obviously the free radicals are not associated with the 285 mμ peak.

Samples irradiated with far ultra-violet show a considerable decrease in electrical resistance from that of the original saran sample (resistivity 10^{15} ohm cm.). Thus sample *C* of Fig. 1 has a thousand-fold smaller resistance than sample *A*. Subsequent irradiation with near ultra-violet influences the resistivity only slightly. The irradiated samples are photoconducting when excited by light below 300 mμ, and the photocurrent is proportional to the intensity of exciting light. Momentary illumination with the intermediate pressure lamp lowers the resistance to a hundredth that in the dark. Additional near ultra-violet irradiation increases the photoconductivity still further, while heating at 100° C. of previously irradiated samples lowers markedly the photoconductivity. It appears, therefore, that photoconductivity is associated with trapped unpaired electrons.

Interesting electrical effects are produced by irradiating two adjacent areas with the unfiltered intermediate pressure lamp for different lengths of time. For example, a portion of the film is irradiated for 5 min. and the whole sample is irradiated for 10 min. so that a sharp boundary is produced. Dusting with a mixture of charged powders (sulphur and red lead) reveals that negative charges lie mainly along a line in the less-irradiated region close to the boundary while positive charges lie mainly along a line close by in the more-irradiated region. The lines of opposite charge are separated by a thin neutral zone. This *p*–*n* junction exhibits rectification properties when illuminated with far ultra-violet, but does not do so in the dark. The presence of the neutral zone is also revealed photometrically. The samples show a colourless non-fluorescent line between adjoining areas, suggesting that a photochemical product migrates to the less-irradiated portion and reverses the effects of prior irradiation. An oxidation-reduction process might be the basis of this effect.

CHEMISTRY

Effect of Chloride Concentration on the Aqueous Corrosion of a Magnesium Alloy

AT each nuclear power station of the Central Electricity Generating Board, the spent-fuel elements will be stored under water for about one hundred days, by which time their radioactivity will have decayed sufficiently to permit them to be removed for reprocessing of the uranium fuel. The water in each cooling pond will be maintained at about *p*H 11·5 by adding caustic alkali to minimize corrosion of the magnesium alloy can (*A*12). Although corrosion should be slight, it is still, however, important, since the corrosion product is radioactive due to the presence of active isotopes developed under irradiation from impurities in the magnesium alloy. In addition, accelerated corrosion can be expected on about 50 per cent of the cans in the pond due to carbon deposited on their surface from the carbon dioxide coolant during reactor operation. This type of accelerated corrosion is very sensitive to the presence of chloride ion in the water; the critical level for rapid attack has been estimated from corrosion tests as less than 10 p.p.m.[1]. Since all the power stations are sited near or on the coast, and most have uncovered cooling ponds, the possibility of enhanced corrosion, due to chloride pick-up, is very real, and an electro-chemical assessment of the effect of chloride and carbon on magnesium alloy corrosion is in progress.

The experimental method involves potentiostatic polarization runs from −2·0 V. cathodic to + 2·0 V. anodic versus a saturated calomel electrode, at a rate of 0·17 V./min., the current and potential values being plotted simultaneously on an X–Y recorder.

Fig. 1 compares the result obtained using an annealed and pickled magnesium alloy specimen with that obtained from a specimen having a carbon deposit. The runs were carried out in a synthetic pond water solution containing 200 p.p.m. sodium hydroxide and 530 p.p.m. sodium carbonate.

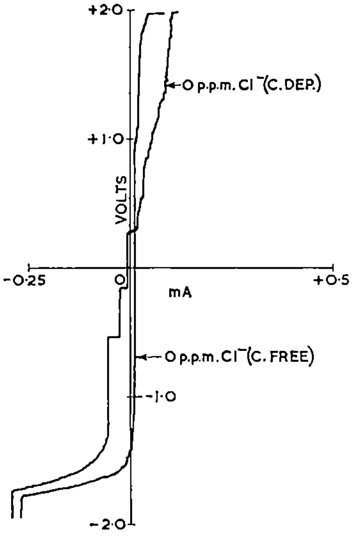

Fig. 1. *A*12 alloy. Effect of carbon-deposition

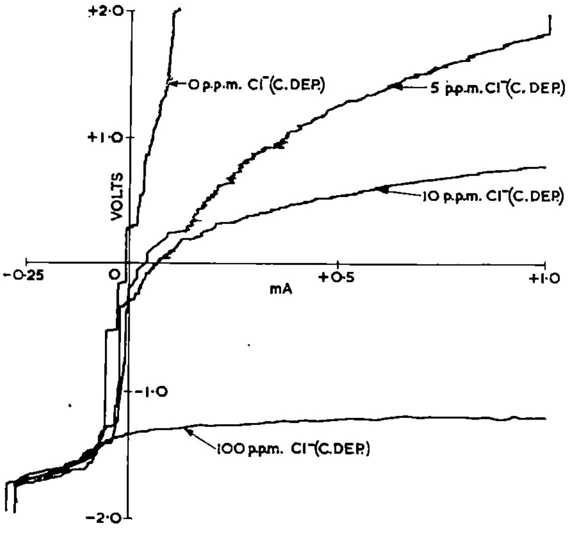

Fig. 2. *A*12 alloy with carbon-deposition. Effect of chloride-level

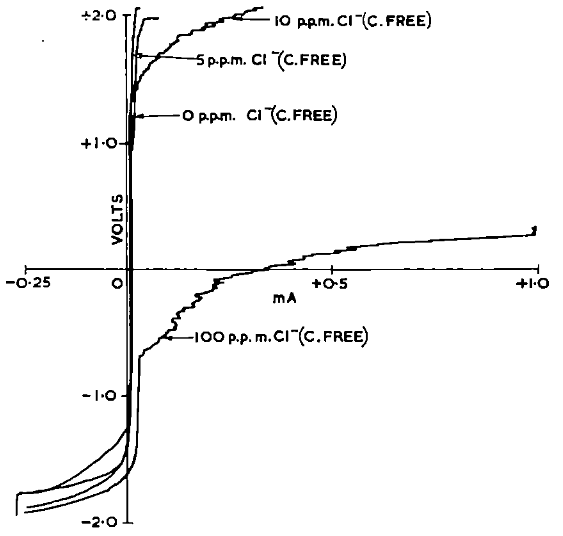

Fig. 3. *A*12 alloy annealed and pickled. Effect of chloride-level

In Fig. 2, results are shown for a number of specimens with carbon deposition, in the same solution but at various levels of added chloride. These may be compared with the corresponding effect of chloride concentration on runs with annealed and pickled specimens in Fig. 3.

From these results it may be seen that while chloride exerts an effect on the behaviour of annealed and pickled magnesium alloy specimens at levels of 10–15 p.p.m. and above, the corresponding level for specimens with a carbon deposit is much lower, and is about 4 p.p.m.

A New Inorganic Reaction: Nitric Acid–Hydrazoic Acid

Reaction of trivalent nitrogen with the azide ion, usually called the 'nitrite-azide reaction', is generally known and has been a subject of recent detailed investigations[1–4]. This azide reaction has been considered to be specific for trivalent nitrogen even in strongly acidic media, and the fact that certain reactions of pentavalent nitrogen (for example, oxidation processes of nitric acid, lead chamber process) are stopped by the addition of azide ions has been accepted as a proof that they proceed through the trivalent nitrogen[5].

Now it has been found that pentavalent nitrogen compounds react with hydrazoic acid in strongly acidic solutions. The reaction was studied polarographically, and the reaction products were analysed by means of gas chromatography. The experiments were performed with sodium nitrate and sodium azide added to the strongly acidic solution. The course of the reaction can be followed polarographically either by means of the nitronium ion waves which appear in 15 *M* and more concentrated sulphuric acid[6], or by means of the wave of hydrazoic acid which is well developed in 8 *M* and more concentrated sulphuric acid solutions[7]. The stoichiometry of the reactants is nitric acid : hydrazoic acid = 1 : 2 and the products are a gaseous mixture of nitrogen, nitrous oxide and in some cases nitric oxide. The rate of the reaction is influenced markedly by the acidity of the reaction medium. When using sulphuric acid the following regions can be distinguished: with more than 13 *M* sulphuric acid the reaction proceeds so quickly that its time-course in the solution cannot be followed polarographically. In Fig. 1 it is seen that after addition of nitrate to the azide solution in sulphuric acid the azide wave with $E_{1/2} = 0{\cdot}7$ V. disappears and a new wave is formed with $E_{1/2} = -0{\cdot}9$ V. against a saturated mercurous sulphate electrode in 17 *M* sulphuric acid. This new wave is independent of time (cf. Fig. 1, curves 2 and 3) and can be easily removed by passing nitrogen through the solution (cf. curves 4 and 5). By further addition of nitrate, two waves are obtained which correspond to the depolarization effects of nitrites in the same medium[6] (Fig. 2). Below 13 *M* sulphuric acid the homogeneous kinetics of removing the hydrazoic acid from the solution can be followed after addition of nitrate (Fig. 3). The wave of hydrazoic acid is somewhat distorted after the addition of nitrate. This is due to the indistinct depolarization effects of nitrates in this medium which are manifested by shifting the hydrogen discharge towards the positive potentials and which are superimposed to the hydrazoic acid wave.

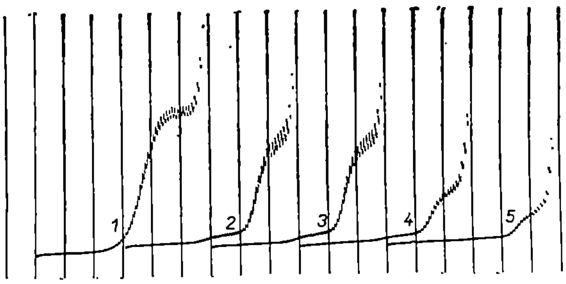

Fig. 1. Course of the hydrazoic acid–nitric acid reaction at acidities higher than 13 *M* sulphuric acid. 1, 10 ml. 14·5 *M* H_2SO_4 + 0·4 ml. 0·1 *M* NaN_3; 2, + 0·2 ml. 0·1 *M* $NaNO_3$; 3, curve 2 after standing for 10 min.; 4, nitrogen passed for 30 sec.; 5, nitrogen passed for another 1 min. *S* = 1 : 40; saturated mercurous sulphate electrode; from 0·0 V.; 200 mV./absc.

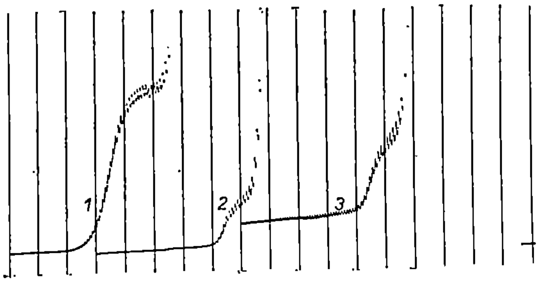

Fig. 2. Influence of nitrate on the product of hydrazoic acid–nitric acid reaction at acidities higher than 13 *M* sulphuric acid. 1, 10 ml. 14·5 *M* H_2SO_4 + 0·4 ml. 0·1 *M* NaN_3; 2, + 0·2 ml. 0·1 *M* $NaNO_3$; 3, + 0·1 ml. 0·1 *M* $NaNO_3$. *S* = 1 : 40; saturated mercurous sulphate electrode; from 0·0 V.; 200 mV./absc.

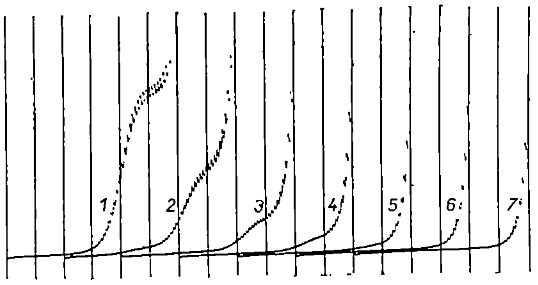

Fig. 3. Course of the hydrazoic acid–nitric acid reaction at acidities lower than 13 *M* sulphuric acid. 1, 10 ml. 13·0 *M* H_2SO_4 + 0·4 *M* NaN_3; 2–7, after addition of 0·2 ml. 0·1 *M* $NaNO_3$, the curves recorded at 3-min. intervals. *S* = 1 : 40; saturated mercurous sulphate electrode; from 0·0 V.; 200 mV./absc.

From the experimental results it follows that the reaction proceeds in three steps :

$$HN_3 + NO_2^+ \xrightarrow{k_1} 2NO + N_2 + H^+ \qquad (1)$$

$$2NO + NO_2^+ + 2H^+ \xrightarrow{k_2} 3NO^+ + H_2O \qquad (2)$$

$$3 \times (NO^+ + HN_3 \xrightarrow{k_3} N_2O + N_2 + H^+) \qquad (3)$$

$$4HN_3 + 2NO_2^+ \longrightarrow 4N_2 + 3N_2O + H_2O + 2H^+ \qquad (4)$$

Reaction (3), which is the known 'nitrite-azide' reaction, proceeds very rapidly even at low acidities and its rate increases with the acidity of the medium[1–4]. Hence it follows that in the strong acid medium which was used in the present experiments the rate of this reaction exceeds by far the rate of reactions (1) and (2). At acidities lower than 13 *M* sulphuric acid the rate-determining step is reaction (1), which is followed by rapid reactions (2) and (3) leading to the overall reaction (4). In the region above 13 *M* sulphuric acid the reaction (1) proceeds very quickly, $k_1 > k_2$, and the scheme is more complicated. From the 2 moles of nitronium ions (taking the stoichiometry according to (4) for $4HN_3 + 2NO_2^+$ . . .) more than one mole can be consumed in the reaction (1) so that less than 1 mole of nitronium ions is left for reaction (2), and consequently a surplus of nitric oxide is formed which cannot be consumed in reaction (2). This is shown in Fig. 1, where the wave with $E_{1/2} = -0{\cdot}9$ V. corresponds to nitric oxide (as mentioned above the wave can be easily removed by bubbling nitrogen through the solution or by adding the nitrate, which leads to the formation of species of trivalent nitrogen according to (2) (Fig. 2). These conclusions in both concentration regions of sulphuric acid were confirmed quantitatively by gas-chromatographic analysis of the reaction products.

The full report of this work including further experiments will be published in *Collection of Czechoslovak Chemical Communications.*

Spin Resonance and Electrical Conductivity of Indole-Iodine

Indole and iodine form a black complex that exhibits a strong electron spin resonance signal[1]. The interpretation that has been given is that indole, if complexed with a small acceptor such as iodine, may act as an especially strong electron donor due to the negative formal charge that exists on carbon 2 and 3.

A number of other iodine complexes also show strong spin resonance signals[2,3]. They also have a rather high electrical conductivity, at least for organic compounds. For the perylene and pyrene complexes, the spin resonance signal appears to be due to charge carriers[2]. On the other hand, this appears not to be true for the carotene complex[3]. Results presented here indicate that this is also not true for the indole-iodine complex, since there appears to be no correlation between the dependence on temperature of the spin resonance and that of the conductivity.

Spectra were taken on Varian *V*-4500 equipment modified to exhibit second derivatives[4]. The *R-F* power-level was approximately 3 mW., at which point the sample exhibited no saturation.

The spin resonance signal is slightly asymmetrical at low temperatures. It has a *g*-value of 2·0036 ± 0·0006. The line-width changes with temperature as indicated in Fig. 1. Since second derivatives were recorded, the number of free electrons was taken as proportional to $(\Delta H)^3 yT$, where y is the peak ordinate of the spectrum and T is the absolute temperature. The factor T is introduced to correct for the differences in distribution between the upper and lower spin states at different temperatures. The absolute number of unpaired spins was estimated by comparing the signal with a known amount of diphenylpicrylhydrazyl (DPPH).

Temperature was varied by running a stream of nitrogen at various temperatures past the sample. A thermocouple was inserted 1 in. from the sample and the assumption was made that the thermocouple measured the sample temperature when repeated runs showed no variation when taken over at least a 10-min. interval. In addition, equilibrium was checked by taking points on both increasing and decreasing temperature runs. The results (Fig. 2) indicate a lowering of the number of spins as the temperature is lowered.

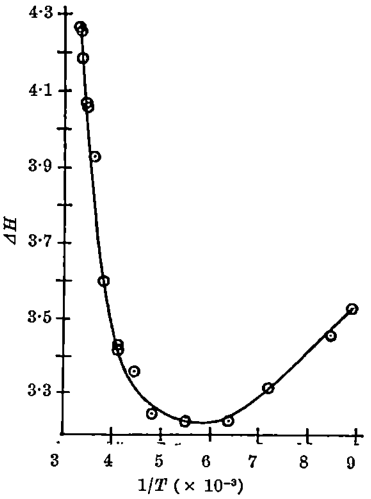

Fig. 1. Line-width in oersteds versus inverse temperature in inverse degrees K. The line-width is taken as the separation of the points of maximum slope of the absorption

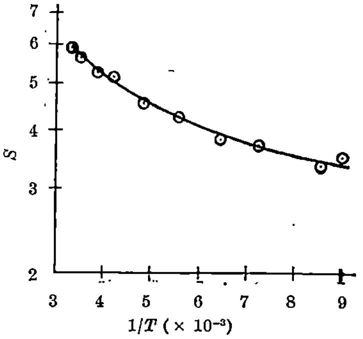

Fig. 2. Number of spins in 10^{19} spins/gm. versus inverse temperature

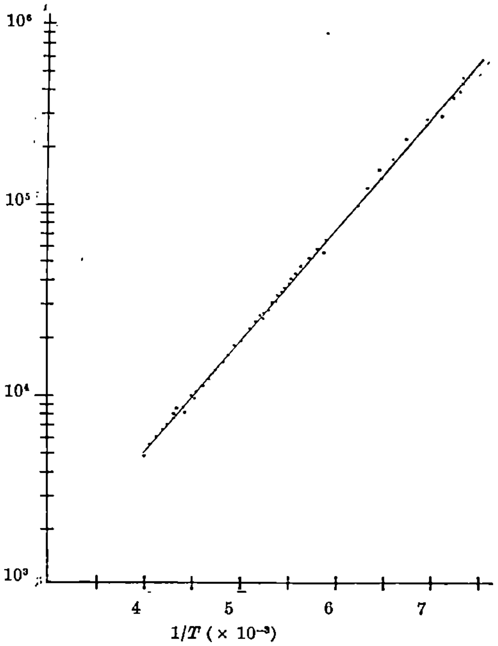

Fig. 3. Resistivity in ohm.–cm. versus inverse temperature

The electrical conductivity was measured on a sample that had been compressed between two brass screws that fit tightly into a 'Pyrex' tube of internal diameter 3·5 mm. Compression was applied and continued until changes in the electrical conductivity could be accounted for solely on the basis of changes in length of the sample. The brass screws served as electrodes, and the resistance was measured by a standard bridge arrangement. Results are shown in Fig. 3 and yield an activation energy of 0·11 eV.

A four-electrode method was also used and gave the same activation energy provided that the current density was sufficiently high. It was noted that below a current density of approximately 2×10^{-2} μamp.-mm.$^{-2}$ the resistivity was non-ohmic and followed a $V \sim i^{0 \cdot 8}$ law.

It may be seen that no correlation appears between the spin resonance characteristics and those of the electrical conductivity. The spin resonance signal thus does not appear to be due to charge carriers. However, no interpretation of the signal is evident at present.

Dependence on Temperature of the Distribution of Cations in Oxide Spinels

THE fact that the cations in the typical spinel A_2BO_4 can be distributed in the so-called normal manner $A_2{}^{\mathrm{VI}}B^{\mathrm{IV}}O_4$, in the inverse manner $(AB)^{\mathrm{VI}}A^{\mathrm{IV}}O_4$, or 'randomly' with *A* and *B* ions statistically distributed over the sites, has long been used to characterize spinel structure phases. Verwey and Heilman[1], Gorter[2] and Romeign[3] have presented many data and lists on the 'type' of a particular spinel. Recent crystal field theory has also attempted to explain the position of a cation in oxide spinels[4]. Certain phases, for example $NiAl_2O_4$, have been characterized as partially inverse or even quantitatively as '85 per cent inverse', the cation distribution being $(Ni_{0\cdot15}Al_{0\cdot85})^{\mathrm{IV}}(Ni_{0\cdot85}Al_{1\cdot15})^{\mathrm{VI}}O_4$. There is in addition, of course, possible ordering on the octahedral and tetrahedral sites in phases such as $LiAl_5O_8$.

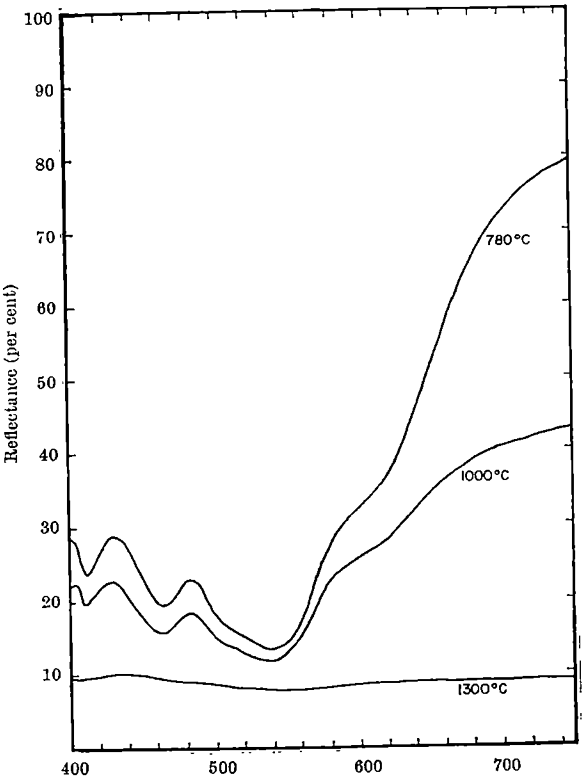

Fig. 1. Reflectance spectra of Co_2GeO_4 (with respect to MgO) samples. 780° C. sample prepared at 1,000 bars, then heated to 1,170° and 1,300° C.

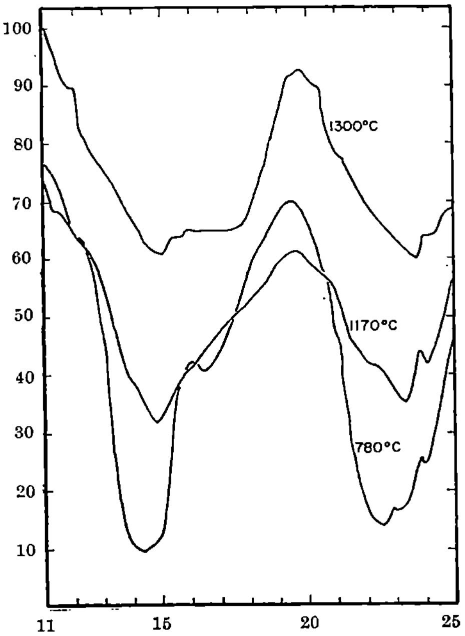

Fig. 2. Infra-red absorption patterns of Co_2GeO_4 samples after different heat treatments

It is the purpose of this communication to direct attention to the fact that in an extensive series of experiments it has been shown that in the majority of spinels, including very common ones, the cation distribution is a function of the temperature and pressure of formation. The following phases have been prepared and equilibrated in the temperature-range 400–1,800° C. and pressure-range 1–100,000 atm.:

Ni_2GeO_4, Co_2GeO_4, $NiAl_2O_4$, $MgAl_2O_4$, Zn_2TiO_4, Co_2TiO_4, 'Ni_2TiO_4', $CdGa_2O_4$, $ZnGa_2O_4$, $NiCa_2O_4$, $LiAl_5O_8$, etc.

The change of the cation distribution has been characterized by the correlation of four properties: unit cell dimensions, X-ray intensities, reflectance spectra in the visible region and infra-red absorption spectra from 11–25μ. Figs. 1 and 2 compare the lowest temperature, high-pressure form of Co_2GeO_4 with the same sample at higher temperatures at 1 atm. There is a very substantial change from a nearly perfect inverse state at low temperature to a substantially normal state at high temperature. The actual assignments of different infra-red absorption bands to various modes involving cation-anion dipoles with the cations changing co-ordination has been shown to be a complex but useful problem[5]. Substantial changes were found for each of the phases mentioned.

Mutual crystalline solubilities of many spinels have also been studied as a means of showing the cation distribution. Different degrees of deviation from ideality at different temperatures (for the same system) indicate the relation between the temperature and cation distribution in spinels. The mutual crystalline solubility relations between Ni_2TiO_4–Zn_2TiO_4 can likewise be explained by the temperature dependence of the degree of 'normalcy' of the 'Ni_2TiO_4', which does not form a compound at all. At higher and higher temperatures more and more nickel enters the tetrahedral sites, permitting 'nearly pure' Ni_2TiO_4 to be prepared in normal structure.

There is still some question as to whether or not all these reactions are reversible and whether we have true second-order phase changes over a wide temperature-range, with the degree of order determined by the temperature.

It is clear from these results that no spinel can be adequately characterized by reference to a table since the temperature and pressure of its formation determine (either stably or metastably) the cation distribution. The results also point to the necessity of presenting temperature-dependent functions for each ion as an essential refinement in crystal field approaches to the problem[4].

This work forms part of the studies in crystal chemistry supported by the U.S. Army Signal Corps under Contract No. *DA*–36–039–*SC*–85311.

Reaction of Ethane with a Clean Rhodium Film

I have observed that when ethane at low pressure ($1 \cdot 2 \times 10^{-2}$ torr) comes in contact with a 27° C. rhodium film which was prepared in ultra-high vacuum (1×10^{-9} torr), it will decompose to yield gaseous methane and an adsorbed residue with a composition of $CH_{1 \cdot 5}$. Others[1,2] have observed this cracking reaction to occur at temperatures above 160° C. on metal surfaces of unknown cleanliness.

The rhodium film was prepared in ultra-high vacuum by pulse evaporating[3] a small coil of 0·005 in. diameter, 99·99 per cent pure rhodium wire in the centre of a 4 in. diameter spherical 'Pyrex' glass reaction vessel which had been baked at 450° C. for 18 hr. The reaction vessel was held at 100° C. during the film deposition. The average film thickness, measured at the completion of an experiment by X-ray emission spectroscopy, was found to be about 30 Å. in most cases. The volume of the system was about 900 c.c.

After the film was deposited, the reaction vessel was isolated from the pumping system by closing a metal valve (Granville-Phillips Co., Pullman, Washington). Five minutes were allowed for the 0·090-in. diameter filament leads to cool below 100° C. Mass spectrometrically pure ethane was admitted through a glass break-seal. The pressure in the reaction vessel was followed by a thermocouple gauge which was calibrated against a McLeod gauge for each gas present and for mixtures thereof. At various intervals, the reaction was quenched by freezing out the ethane in a cold finger with liquid nitrogen and the residual pressure measured.

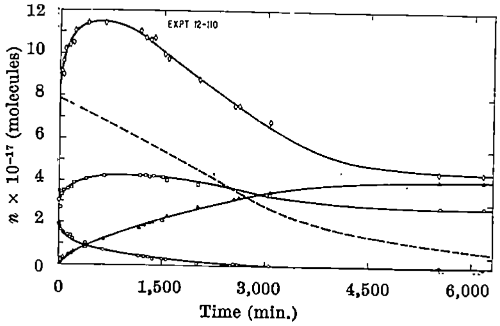

Fig. 1. Rate of decomposition of ethane on a 27° C. rhodium surface and the rate of product formation. ○, $n_{C_2H_6}$; △, n_{CH_4}; □, n_C; ◇, n_H. – – –, H/C (surface)

When the liquid nitrogen non-condensable pressure attained a constant value, it was assumed that the reaction had ceased. At this point the gases in the reaction flask were removed and analysed with a mass spectrometer. In all cases only methane was found.

These experiments were also carried out at a film temperature of 100° C. The films used at 100° C. were deposited on a 100° C. glass substrate.

A blank experiment was performed in which ethane was admitted to a baked-out reaction vessel at 100° C. There was no decomposition after 47 contact hr.

The results from a typical experiment carried out on a rhodium film with an average thickness of 30 Å. at 27° C. are shown in Fig. 1. The number of carbon atoms and hydrogen atoms present on the film at time *t* were calculated from the initial amount of ethane and the amount of ethane and methane present at time *t* as determined from the thermocouple gauge readings.

Plotting the log of the ethane pressure against time yielded a straight line. Thus, the disappearance of ethane obeys the first-order rate equation:

$$dn_{C_2H_6}/dt = -kn_{C_2H_6}$$

with an initial rate constant of $2 \cdot 13 \times 10^{-3}$ min.$^{-1}$. The rate of disappearance of ethane on a rhodium film at 100° C. also obeyed a first-order equation with a rate constant of about 0·5 min.$^{-1}$. The temperature dependence of the initial rate constant gives an Arrhenius activation energy of 16 ± 1 kcal./mole for the disappearance of ethane. The (H/C) surface ratio is about 1·5 at the end of the reaction for both film temperatures. When deuterium was added, the residue desorbed from the rhodium film as deuterated methane, indicating the presence of only monocarbon fragments on the surface.

The addition of oxygen to a clean rhodium film at 100° C. was found to inhibit the subsequent decomposition of ethane. The rate of disappearance of ethane was decreased by a factor of ten over that for a clean film at 100° C.

These experiments show that ethane will crack on a clean rhodium surface at room temperature. The rate of reaction is a sensitive function of both the surface temperature and surface cleanliness.

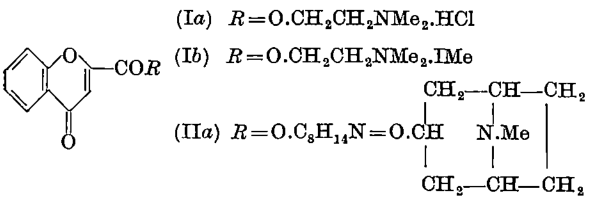
Some New Esters of Chromone-2-Carboxylic Acid

WITH the view of further pharmacological work by one of us (K. V.-B.), it was decided to synthesize certain esters of chromone-2-carboxylic acid, not previously described[1–4]. The following compounds were obtained: dimethylaminoethyl-chromone-2-carboxylate hydrochloride (I*a*), the methiodide of the base (I*b*); tropyl-chromone-2-carboxylate (II*a*), its hydrochloride (II*b*), methobromide (II*c*) and methiodide (II*d*):



(I*a*) $R = O.CH_2CH_2NMe_2.HCl$

(I*b*) $R = O.CH_2CH_2NMe_2.IMe$

(II*a*) $R = O.C_8H_{14}N = O.CH(CH_2{-}CH{-}CH_2)(CH_2{-}CH{-}CH_2)N.Me$

(II*b*) $R = O.C_8H_{14}N.HCl$; (II*c*) $R = O.C_8H_{14}N.BrMe$;

(II*d*) $R = O.C_8H_{14}N.IMe$; (III*a*) $R = OH$; (III*b*) $R = Cl$

Chromone-2-carboxylic acid (III*a*), white needles from alcohol–water, melting point 256–259° (decomposes) (lit. (1), m.p. 256–263° (decomp.)), and its chloride (III*b*), white needles from petroleum ether (50–65°), m.p. 105–106° (lit. (3), m.p. 105·5–106·5°) (found: Cl, 16·6. Calc. for $C_{10}H_5O_3Cl$: Cl, 17·0) were synthesized following the technique of Zagorevskii *et al.*[3].

(I*a*) was obtained by treating 1·5 moles of (III*b*) with 1 mole of 2-dimethylaminoethanol, for 4·5 hr. in toluene by refluxing; white needles from methanol, m.p. 202–204° (decomp.); R_F: *n*-butanol/acetic acid/water (6 : 1 : 2; v/v) (Solvent *A*), 0·35; *n*-butanol/2 *N*-hydrochloric acid (1 : 1; v/v; upper phase) (Solvent *B*), 0·70 (found: C, 56·4; H, 5·5; Cl, 12·0; N, 4·8. $C_{14}H_{15}NO_4.HCl$ requires C, 56·5; H, 5·4; Cl, 11·9; N, 4·7).

(I*b*) was obtained by treating 1·5 moles of (III*b*) with 1 mole of choline chloride, for 8 hr. in toluene by refluxing. The crude methochloride was transformed into methiodide by adding sodium iodide in methanol; white plates from methanol, m.p. 224–226° (decomp.); R_F: Solvent *A*, 0·59 and *B*, 0·56 (found: C, 44·4; H, 4·7; I, 31·0; N, 3·4. $C_{15}H_{18}INO_4$ requires C, 44·7; H, 4·5; I, 31·5; N, 3·5).

(II*a*) was obtained by treating 1·5 moles of (III*b*) with 1 mole of tropine in pyridine, left overnight at room temperature, poured into dilute potassium carbonate and extracted with chloroform; white prisms from petroleum ether (50–55°), m.p. 107–109°; R_F: Solvent *A*, 0·68 and *B*, 0·72 (found: C, 68·8; H, 6·0; N, 4·4; $C_{18}H_{19}NO_4$ requires C, 69·0; H, 6·1; N, 4·5).

(II*b*) was obtained by bubbling dry hydrogen chloride into a solution of (II*a*) in ether; white needles from methanol-ether, m.p. 247–251° (decomp.); R_F: Solvent *A*, 0·68 and *B*, 0·73 (found: C, 58·8; H, 6·2; Cl, 9·4; N, 4·0. $C_{18}H_{19}NO_4.HCl.H_2O$ requires C, 58·8; H, 6·0; Cl, 9·6; N, 3·8).

(II*c*) was obtained from (II*a*) dissolved in acetone, by adding methyl bromide at room temperature; white plates from methanol-ether, m.p. 270–271° (decomp.); R_F: Solvent *A*, 0·60 and *B*, 0·60 (found: C, 53·6; H, 5·8; Br, 19·0; N, 3·4. $C_{19}H_{22}BrNO_4.H_2O$ requires C, 53·5; H, 5·7; Br, 18·7; N, 3·3).

(II*d*) was obtained from (II*a*) in a similar way to (II*c*), but using methyl iodide; white plates from aqueous ethanol, m.p. 276–277° (decomp.); R_F: Solvent *A*, 0·60 and *B*, 0·60 (found: C, 49·8; H, 5·0; I, 27·7; N, 3·0. $C_{19}H_{22}INO_4$ requires C, 50·1; H, 4·9; I, 27·9; N, 3·1).

The melting points were determined on a Kofler hot stage (Leitz, *M*350). The chromatograms were run on Whatman No. 1 paper by ascending technique, at 24°. The spots were developed with Draggendorff's reagent[5].

We are grateful to Prof. Mario R. Falco for advice and encouragement during this research.

Note added in proof: We have now obtained the original work of Zagorevskii *et al.* (*J. Gen. Chem. U.S.S.R.*, 29, 2267; 1959) in which the ester (I*a*) is described. This compound is not mentioned in *Chem. Abs.*, 54, 11007 (1960).

BIOCHEMISTRY

Structure of Feather Keratin

FEATHER keratin is the outstanding protein fibre structure that still lacks an interpretation generally acceptable in any detail. It has long been known[1] that its X-ray diffraction diagram is of a β-type with the strong indication that the residue-length is only about 3$\frac{1}{10}$ Å. instead of the 3⅓ Å. and 3½ Å. found in β-keratin and silk fibroin, and it has corpuscular properties besides[2], especially as demonstrated in the paper by Bear and Rugo[3], supported also by physico-chemical studies and the finding that the unit is probably a cyclic polypeptide[4]. In Bear and Rugo's scheme the structure is based on a net of corpuscular units the nodes of which are at approximately (0, 0), (0, ½), (½, ¼), and (½, ¾), the plane of the net containing both the main-chain and side-chain directions. Continuing from this point and associated observations by the same authors, it is the purpose of this communication to state what we believe to be a very strong case for the structure of the corpuscles themselves. The principal steps in the argument may be summarized as follows :

(1) There are three polypeptide β-configurations ('pleated sheets')[5] with interchain CO . . . NH hydrogen bonds that are linear (see, for example, ref. 6 for our own style of models illustrating this), and in these the amino-acid residue-lengths are approximately 3½ Å., 3⅓ Å., and 3$\frac{1}{10}$ Å., respectively. In the first two the chains are anti-parallel and parallel dyad screws, respectively, and they satisfy the requirements of silk fibroin and β-keratin. In the third the chains are 'parallel polar'; that is, they run in the same direction but are not screws, each chain having all its CO groups on one side and all its NH groups on the other side. It is a fair hypothesis that

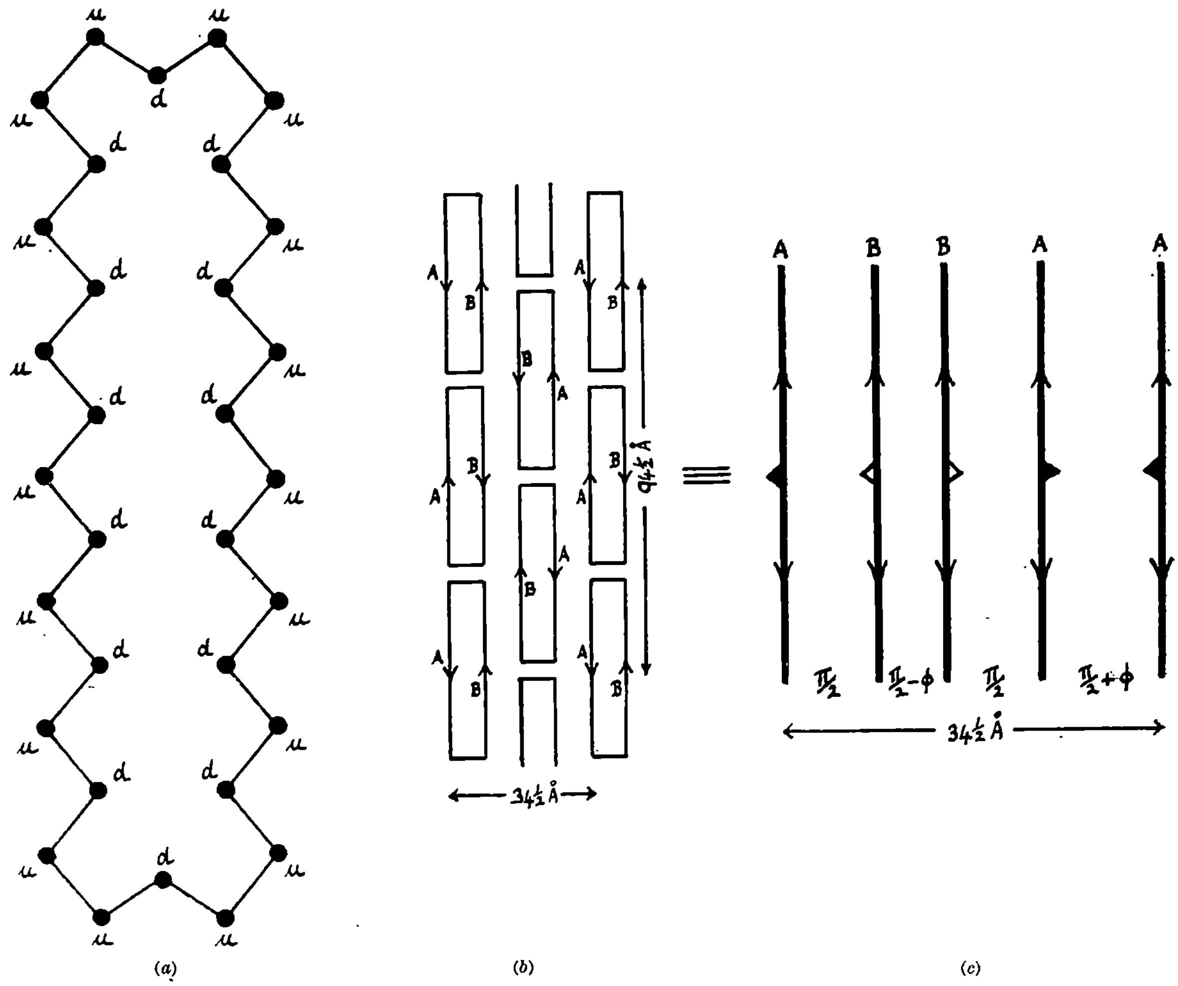

Fig. 1. Diagrammatic representation of (*a*) the proposed 32-residue loop-corpuscle, α-carbons being indicated by black dots and the bonds to β-carbons by *u* (up) and *d* (down); (*b*) the arrangement of polypeptide chains in conformity with the net pattern of Bear and Rugo; and (*c*) the equivalent scheme of chains for the purpose of deriving the equatorial intensities

this third arrangement, with its residue-length of about $3\frac{1}{10}$ Å., is the basis of the third known natural β-structure, that of feather keratin[6,7].

(2) The inference receives immediate strong support from the striking contrast between the meridional reflexions of fibroin and β-keratin on one hand and of feather keratin on the other. In relation to the axial sub-unit of a pair of consecutive residues, the former show no 1st order but a strong 2nd order (and also a 6th), while the latter shows a strong 1st order but no 2nd order (and no 6th either).

(3) Feather keratin contains a high proportion of proline residues (about one-tenth)[8], and these fit readily into the parallel-polar configuration[9], but not without strain into the other two β-configurations. We suggest that it is indeed the proline residues which impress the parallel-polar configuration on the feather keratin structure.

(4) Apparently the only other chain-configuration which has a residue-length of about 3·1 Å. and which can also incorporate proline without strain is the trigonal helix that is the basis of collagen[9]. A collagen-type structure for feather keratin has in fact been advocated by Ramachandran[10], but in our view it is quite ruled out by the infra-red data. Collagen has a unique, 'diagnostic' NH-stretching frequency at 3,330 cm.$^{-1}$ as compared with the 3,300 cm.$^{-1}$ found with the other fibrous proteins including feather keratin, and its other CO and NH frequencies are also above the range found with accepted β-structures and feather keratin[11].

(5) In conformity with Bear and Rugo's Fig. 6, we propose the loop-corpuscle structure represented diagrammatically, and most briefly for the present, by Fig. 1, for which we have constructed satisfactory scale-models both of our own and of the Courtaulds type. There are 32 residues per loop, and two features to be specially noted are: (1) that, looking transversely, the β-carbons on opposite sides are in register as well as the α-carbons; (2) that the CO groups all point upwards along one side but downwards along the opposite side, thus cancelling out the polar imbalance and any bending tendency that might otherwise accrue.

(6) Bear and Rugo's net in any event accounts most plausibly for the dominant meridional reflexion at 23·6 Å., and now our own calculations show also that, on the basis of Fig. 1*a* and the chemical-analytical[8] average residue-weight of 98·5, the reflexion near 6·2 Å., corresponding to the 'first order' of the characteristic residue-pair, should be about 150 times as strong as the 'second and sixth orders' near 3·1 Å. and 1·03 Å., respectively. (The observed intensities are strong : 0 : 0.)

(7) The equatorial reflexions are the first four orders of about 34½ Å., plus a fuzzy reflexion apparently corresponding to the CO . . . NH linkage transverse to the loop. The former change with the water-content and various swelling pre-treatments[3], and they have still to be worked out in detail; but preliminary calculations based on effectively four chains of appropriately different weights and separations, as in Fig. 1*c*, are already in sufficiently good agreement to indicate that this is probably the correct approach.

(8) Bear and Rugo's requirement of a plane-net structure, and the vagueness of the CO . . . NH linkage, are explained at once by our models, which show that continued regular superposition of loops will in general be obstructed by the proline residues. With one special arrangement of the latter, though, correct 'sandwich-pairs' are possible, but nothing thicker, suggesting a limiting corpuscle-weight of perhaps about 6,400 as compared with Woodin's[4] physico-chemical estimate of about 10,000.

(9) Finally, the calculated density of our structure is 1·32, compared with the observed value of 1·27 (ref. 12). The difference is in the right direction for a high polymer and is quite unobjectionably small.

Two other proposed structures for feather keratin are those of Krimm and Schor[13] and of Fraser and MacRae[14]; but we believe that the one outlined here offers a better interpretation of the experimental facts, as we hope to show more fully in a later publication.

Simultaneous Determination of Dextran and Glucose in Serum

IN the course of an investigation on the mechanism of 'anaphylactoid' reaction in rats, the need was felt for an accurate and simple procedure for the simultaneous determination of dextran and glucose in small amounts of serum. For this purpose the following method was developed. It utilizes the *o*-toluidin – glucose coupling reaction[1], producing a green colour suitable for colorimetric measurement. Dextran is precipitated from the serum by the *o*-toluidin – acetic acid reagent followed by hydrolysis and the colour reaction. Serum glucose is directly determined from the supernatant layer of the dextran precipitate.

Blow 0·1 ml. serum, containing 25–400 μgm. dextran, into 10-ml. glass-stoppered test-tubes containing 4 ml. of *o*-toluidin reagent (6 per cent *o*-toluidin in glacial acetic acid prepared immediately before use). Put the tubes in a refrigerator at 4° C. for 30 min. Centrifuge (3,500 r.p.m.) for 30 min. Decant the supernatant carefully into another test-tube. Place the latter in a boiling water-bath for exactly 8 min. Cool and read the optical density in a spectrophotometer or filter photometer at or near 625 mμ. A standard glucose solution is treated in the same way as serum.

The tubes containing the precipitated dextran are dried by placing them in an inverted position on a towel. 0·2 ml. of 4 *N* sulphuric acid is added and the precipitate dissolved by shaking. The tubes are loosely stoppered with glass stoppers (secured by a rubber band) and placed in a boiling water-bath for 75 min. After cooling, 8 ml. of *o*-toluidin reagent is added and the contents mixed. After boiling for exactly 8 min. the colour intensity is determined as above. A standard solution of dextran or glucose is carried through the entire procedure. In the latter case the result is multiplied by 0·9 (ref. 2), since 100 mgm. dextran is equivalent to 111 mgm. glucose.

The efficiency of dextran precipitation by the reagent was checked as follows: 0·1 ml. portions of 200, 400, 600, 800 mgm. dextran/100 ml. solutions were pipetted into 4 ml. of 6 per cent *o*-toluidin in acetic acid. After cooling and centrifugation, 20 ml. of 96 per cent alcohol was added to 2 ml. of the supernatant to precipitate the part of the dextran possibly remaining soluble in the reagent. The tubes were kept in the refrigerator overnight and, after centrifugation and decantation of supernatant, an anthrone reaction[3] was carried out with the residue. Sixteen determinations were made, optical densities being read in a Beckman *DU* spectrophotometer. In the range of 200–600 mgm./100 ml., the supernatant contained no anthrone-positive material which could be precipitated with alcohol. The supernatant contained only in the case of the 800 mgm. dextran/100 ml. an average of 1·37 per cent of total dextran.

The adequacy of the hydrolysis of dextran as used by Dimler *et al.*[2] was also investigated. 10, 50, 75, 100, 150 and 200 mgm. dextran/100 ml. solutions in 4 *N* sulphuric acid were kept in a water-bath at 100° C. for 75 min. After cooling, 8 ml. of 96 per cent alcohol were added to 0·8 ml. of hydrolysate, the tubes were kept at 4° C. overnight, centrifuged, the residue was washed once with 96 per cent alcohol and the anthrone reaction carried out. Six triplicate determinations were carried out. Traces of anthrone-positive material were found in 3 tubes, but not in the parallel tubes ;

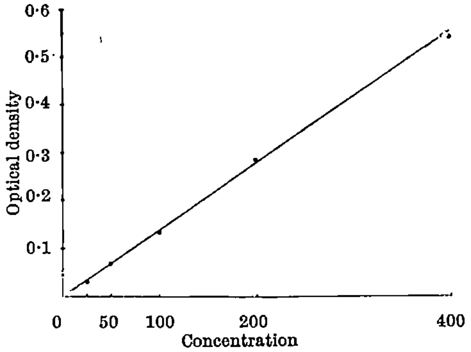

Fig. 1. Colour reactions of dextran solutions in water after hydrolysis. Abscissa: concentration of solutions. Ordinate: optical density determined at 625 mμ in 1-cm. cells in the Beckman *DU* spectrophotometer. Each point is the average of three determinations

therefore extraneous carbohydrate contamination was assumed in these cases.

In Fig. 1 is shown the colour reaction of dextran solutions in water after hydrolysis. There is good agreement with Beer's law within the concentration-range 25–400 mgm./100 ml. Dilution of serum is recommended for higher concentrations.

The coefficient of variation (per cent standard deviation) obtained by 20 parallel determinations on rat serum was 2·7 per cent for glucose at a level of 194 mgm./100 ml. and 2·5 per cent for dextran at a level of 184 mgm./100 ml.

We are indebted to Glaxo Laboratories, Ltd., for a gift of 'Clinical Dextran' used in this work. Dr. G. Szepessy, of the Central Research Laboratory of this University, kindly determined the optical densities.

Emulsifying Capacity of Blood Sera

In view of the suspected link between fat metabolism and atherosclerotic disease, the state and behaviour of the emulsified fats in the blood serum have been the object of numerous investigations. Thus, for example, stabilized emulsions of lipoproteins, of coconut oil, and of olive oil have been added to sera in order to demonstrate the clearing reaction of heparin[1]. It seems, however, that the ability of different sera to emulsify various fats has never been investigated systematically.

In order to test the emulsifying ability of different sera, a simple, reproducible turbidimetric method of measurement has been developed. Briefly, the serum is shaken under controlled conditions with 0·5 per cent olive oil. The optical extinction rises to a maximum with time and then begins to fall; at 37° C. the maximum extinction is reached in about 20 min. The maximum extinction value we termed the 'emulsifying capacity' of the serum. The dispersion of 0·5 per cent olive oil in 0·005 per cent 'Lissapol' (run parallel with the experiments) served as control.

The emulsifying ability of a given serum has been found to be reproducible to within about ± 2 per cent.

Microscopic investigation showed that greater turbidity corresponds to a smaller average oil-droplet diameter.

After the reproducibility of the results was proved beyond doubt, studies have been initiated of the influence of various factors on the maximum turbidity obtained. The following is a summary of the results:

(1) There is an optimum shaking rate of about 200 beats/min. for the development of high turbidity emulsions.

(2) At oil concentrations between 0·1 and 1 per cent the maximum turbidity has been found to be proportional to the logarithm of the oil concentration.

(3) The emulsifying ability of sera from different animals has been found to vary both from animal to animal, as well as from species to species. Thus, sheep and cattle sera show higher emulsifying ability than pig sera; this variation in emulsifying capacity is well outside the variations found with sera from individual animals of the same species.

(4) The type of oil used determines, to a large extent, the maximum turbidity. In general, oils yielding high-turbidity emulsions have high acetyl and iodine numbers, and low viscosity. It must be stressed, however, that these differences are substantially smaller when the experiments are conducted at 37° C., although some differences still persist; thus, coconut oil yields substantially coarser emulsions both at room temperature and at 37° C.

(5) The addition of surface-active compounds exerts a strong influence on the maximum turbidity obtained. I found that in the presence of small concentrations (5×10^{-4} *M*) of surfactive acids (for example, oleic acid) the emulsification decreases, while the addition of the same amount of surfactive bases (for example, long-chain amines) or of neutral surfactants (for example, cetyl alcohol) increases the maximum turbidity. The effect of the surfactant is the same, whether it is added to the serum or to the oil phase.

(6) Diluting the serum up to ten-fold with isotonic phosphate buffer (*p*H 7·2) increases the maximum obtainable turbidity; further dilution results in a decrease of the maximum turbidity. The reasons for this particular behaviour remain to be investigated; they could be attributed tentatively to either changes in the protein surface and/or to viscosity changes.

Examination of some of the physico-chemical properties of the resulting emulsions have shown that:

(1) The electrophoretic mobilities of the oil droplets seemed unchanged by the nature of the surfactant added, a result which warrants further investigation.

(2) The interfacial surface tension is only slightly lowered in the presence of surface-active compounds; the degree of emulsification obtained seems unrelated to the interfacial surface tension.

Clinical investigations are at present being carried out in the Lidcombe State Hospital, Sydney. Although it is too early at present to draw conclusions from the results so far obtained, it is already evident that there are individual variations in the emulsifying abilities of human sera; sera obtained at different times from one and the same person can also show marked variations. Thus, the emulsifying ability obtained with the serum of a given individual invariably decreases after the ingestion of fats. Interesting effects have been observed on intravenous injection of heparin; they will form the subject of a separate communication, as will the details of the work presented here.

Hydrolysis of Fatty Acid Esters of Riboflavin by Pancreatic Lipase

Fatty acid esters of riboflavin, fat-soluble riboflavin derivatives, have been synthesized in our laboratory to widen the application of riboflavin to pharmaceutical and nutritional fields[1–3]. As a fundamental problem of this application, the possibility of enzymic hydrolysis of these esters to riboflavin and fatty acids has to be investigated first. This communication deals briefly with their hydrolysis *in vitro* by pancreatic lipase.

Fatty acid esters were synthesized by esterification of riboflavin with fatty acid chloride, and riboflavin 2′, 3′, 4′, 5′-tetrabutyrate, tetracaprate, and tetrapalmitate were obtained as reported before[1-3]. Pancreatic lipase was supplied by the Nutritional Biochemical Corporation. The activity of the enzyme preparation was checked by using tributyrin and 'Tween 20' as substrate. The reaction mixture consisted of 0·5 ml. of 4 mmole/l. fatty acid ester of riboflavin suspended in 1 per cent polyvinyl alcohol (degree of polymerization: 500), 0·5 ml. of enzyme solution (20 mgm. protein/ml.) and 1·0 ml. of McIlvaine buffer (*p*H 7·3).

The reaction mixture was incubated at 37° C. for 2 hr. with gentle shaking. After incubation, the test solution was analysed by paper chromatography using an upper layer of *n*-butanol/acetic acid/water (4 : 1 : 5, v/v) as a mobile phase. After 10 hr. development at 20° C., the paper was removed and allowed to dry at room temperature in the dark. The paper strip was examined under ultra-violet light, and flavins were detected by their yellow fluorescence.

When riboflavin tetrabutyrate was incubated with pancreatic lipase, yellow fluorescent spots were observed on the paper at R_F values of 0·3, 0·5, 0·6, 0·7 and 0·97. Substances at R_F value 0·3 and 0·97 were identified with riboflavin and riboflavin tetrabutyrate respectively. Substances at R_F values 0·5, 0·6 and 0·7 were supposed to be the intermediate compounds from riboflavin tetrabutyrate to riboflavin. The riboflavin part was eluted with hot water, and the other yellow fluorescent spots were eluted with 98 per cent ethyl alcohol. The amount of flavin in both eluates was measured by the lumiflavin fluorescence method[4]. The enzyme activity was expressed by the amount of free riboflavin split off from fatty acid ester of riboflavin.

Riboflavin tetracaprate and tetrapalmitate were also examined in the same way, and hydrolyses of these substances by pancreatic lipase were compared with each other. The results are shown in Table 1. Among fatty acid esters of riboflavin tested, tetrabutyrate was found to be most easily hydrolysed, followed by tetracaprate and tetrapalmitate. In the case of tetrabutyrate, optimum *p*H and temperature of the enzyme were found at 7·3 and 37° C. respectively.

Table 1. COMPARISON OF HYDROLYSIS OF FATTY ACID ESTERS OF RIBOFLAVIN BY PANCREATIC LIPASE

Substrate	Rate of hydrolysis (per cent)
Riboflavin tetrabutyrate	45·4
Riboflavin tetracaprate	3·4
Riboflavin tetrapalmitate	1·2

Reaction mixture: 0·5 ml. of 4 mmole/l. substrate suspended in 1 per cent polyvinyl alcohol, 0·5 ml. of the enzyme (20 mgm. protein/ml.) and 1·0 ml. of McIlvaine buffer, *p*H 7·3. Incubation: 37° C., 2 hr.

Fatty acids liberated from these esters by the enzyme were checked. For example, in the case of tetrabutyrate, liberated fatty acid in the incubated reaction mixture was extracted with ethyl ether, concentrated, and then analysed by paper chromatography followed by coloration with bromocresol purple[5]. A single spot corresponding to butyric acid was detected.

From these results it was clear that these fatty acid esters of riboflavin could be hydrolysed to riboflavin and the corresponding fatty acid by the enzyme action of pancreatic lipase. Considering also the fact that these esters are effective as riboflavin by the test of animal growth[6], it is considered that these esters may be converted to riboflavin and then act as a vitamin.

It may be noticed that pancreatic lipase can also attack these newly synthesized esters besides substrates hitherto known.

Neutral 17-Ketosteroids in Porcine Urine

IN searching for an experimental animal which, in regard to its steroid metabolism, would be suitable for an investigation into the mechanism of action of certain synthetic steroids, particularly 19-norsteroids, we decided to use the domestic pig. A few preliminary experiments were made, during which we determined, among other things, the concentration of Zimmermann chromogens in the urine of male and female pigs and in the urine of castrated animals, while the influence of chorionic gonadotrophin and adrenocorticotrophic hormone on the excretion of Zimmermann chromogens in adult male pigs was also determined. After these preliminary experiments we started to isolate and identify the substances which produce the Zimmermann reaction.

For this purpose, 5,760 ml. urine from an adult male animal was extracted by the method of Dingemanse *et al.*[1]. Two extracts were obtained:

(*a*) An extract obtained by heating the unacidified urine to about 80° C., during 4 hr., while simultaneously extracting with benzene.

(*b*) An extract obtained by adjusting the urinary residue resulting from treatment of urine as in (*a*) to *p*H 1, after which it was heated to about 80° C., for 4 hr., while simultaneously extracting with benzene.

The former extract, which contained about 660 mgm. 'dehydroepiandrosterone equivalents', was purified by the Girard method, by chromatography over aluminium oxide and over cellulose powder. In this way we obtained four different Zimmermann positive fractions, two of which have so far been completely purified and identified. The first fraction to be isolated was 3-chloro-androst-5-ene-17-one, which was identified as follows:

(1) By paper chromatography (system propylene glycol: methanol/heptane).

(2) By determination of the melting-point (148–152° C.) and the mixed melting-point with authentic 3-chloro-androst-5-ene-17-one (with the aid of the Eimer and Amend apparatus, uncorrected).

(3) By establishing that no acetate is obtained at acetylation.

(4) By infra-red analysis: the infra-red spectrum was completely identical with that of authentic 3-chloro-androst-5-ene-17-one.

(5) By elementary analysis, which yielded the following results: C = 74·68 per cent, calculated for $C_{19}H_{27}OCl$: 74·39 per cent; H = 8·69, calculated for $C_{19}H_{27}OCl$: 8·81; Cl = 11·35, calculated for $C_{19}H_{27}OCl$: 11·58. The extract of 5,760 ml. urine was estimated to contain more than 300 mgm. 3-chloroandrost-5-ene-17-one.

The second 17-ketosteroid found to be present in urine of male pigs is dehydroepiandrosterone, which was identified as follows:

(1) By paper chromatography (system propylene glycol: methanol/heptane).

(2) By determination of the melting-point (138–142° C.) and the mixed melting-point with authentic dehydroepiandrosterone.

(3) By acetylation, which yielded an acetate which was, as judged by its infra-red spectrogram, melting-point and mixed melting-point, identical with authentic dehydroepiandrosterone acetate.

(4) By infra-red spectrometry: the infra-red spectrum was completely identical with that of authentic dehydroepiandrosterone.

(5) The substance produces the reaction with phosphomolybdic acid which, carried out under certain conditions, is specific of unsaturated steroids.

A total quantity of 77·3 mgm. pure dehydroepiandrosterone was obtained from 5,760 ml. urine.

The urinary extract obtained at *p*H 7 in addition contains 1–2 other 17-ketosteroids oxygenated on C_{11}.

The extract obtained at *p*H 1 has so far been examined only with the aid of paper chromatography. It contains several Zimmermann chromogens. The chromogen present in the highest concentration has an R_F value with paper chromatography = R_F dehydroepiandrosterone, or epiandrosterone, respectively (system propylene glycol: methanol/heptane).

We are indebted to N.V. Organon, Oss, Netherlands, from whom we received authentic dehydroepiandrosterone and authentic dehydroepiandrosterone acetate.

We received a quantity of authentic 3-chloro-androst-5-ene-17-one from the Steroid Reference Collection, London, through the courtesy of Prof. W. Klyne. The infra-red spectra were registered under the supervision of Dr. K. v. Lier, of the National Institute of Public Health, Utrecht. We thank Mr. P. Hubers, of the Organic-Chemical Laboratory of the Municipal University of Amsterdam, for carrying out analytical work.

Oxytocinase Activity of Plasma of Pregnant Women

It has been shown[1] that plasma or serum from pregnant women has the power of inactivating oxytocin when incubated with the hormone. This power is thought to be dependent on an enzyme, called oxytocinase. The enzyme inactivates both natural and synthetic oxytocin[2–5]. The rate at which plasma inactivates oxytocin increases with the age of pregnancy[1,4,6–9]. Maximum values are said to be reached around the 36th week of pregnancy, after which they remain at the same level until delivery. After parturition the oxytocinase activity decreases progressively, becoming very low in about one month.

Most of the work on oxytocinase has been performed with biological assays with oxytocin as substrate.

According to Tuppy *et al.*[10], oxytocinase is an aminopeptidase with the power of splitting the peptide-bond between tyrosine and cystine in the oxytocin molecule. With regard to this mode of action, Tuppy *et al.* synthesized a substrate, L-cystine-di-β-naphthylamide, with partly the same molecular configuration as oxytocin and worked out a chemical method for the assay of the oxytocinase activity with this synthetic substrate[11].

The results reported by Tuppy *et al.* with their chemical method are different from those obtained by other authors using biological methods. It must, however, be pointed out that even the values reported by different authors using biological assays are indeed different; the activity at the end of pregnancy is reported to be either 1,000 times or 10 times higher in comparison with the activity at the beginning of pregnancy[9,12]. According to Tuppy *et al.* the oxytocinase activity at the end is about 28 times higher in comparison with the values in the non-pregnant state. These authors could not confirm the results, outlined in the introduction, that maximum values are reached around the 36th week of pregnancy with no increase thereafter. Their values show a steady increase up to the time of delivery. These differences in the values reported probably depend on experimental error.

The present preliminary report deals with the results obtained in assays of oxytocinase activity in pregnant women with both the chemical and a biological method in parallel.

A total of about sixty healthy pregnant women were examined, plasma being the enzyme source and syntocinon and L-cystine-di-β-naphthylamide respectively the substrates. The enzyme reaction occurred under carefully standardized conditions, and the determination of the remaining oxytocic activity was made on rat uterus preparations using a four-point

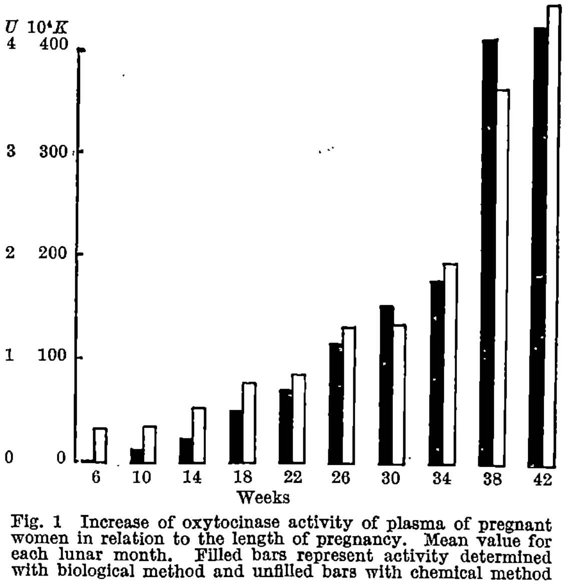

Fig. 1 Increase of oxytocinase activity of plasma of pregnant women in relation to the length of pregnancy. Mean value for each lunar month. Filled bars represent activity determined with biological method and unfilled bars with chemical method

assay with statistical treatment according to Gaddum[13], and Borth *et al.*[14]. Enzyme activity was expressed as $10^4 \times K$; $K =$ the velocity constant according to the formula $K_1 = \frac{1}{t} \ln \frac{a}{a-x}$. In using Tuppy's chemical method I have expressed the enzyme activity as units (U) of Tuppy, 1 mgm. liberated β-naphthylamine per 100 ml. plasma per hr. adopted as 1 U. All estimations were performed in duplicate.

Fig. 1 shows the increase of plasma oxytocinase activity with the length of pregnancy, the activity in each case being determined with biological and chemical method in parallel.

As may be seen, the values obtained with the two methods show on the average the same increase of oxytocinase activity in relation to the length of pregnancy. The results make it probable that the two methods determine identical enzyme activities; this has been questioned earlier. The activity also shows a steady increase up to the time of delivery, which is in agreement with the results of Tuppy *et al.*[11].

Work is now in progress in order to secure these preliminary results and investigate the enzyme activity in abnormal conditions of pregnancy. Attempts to concentrate and purify the enzyme are also in progress.

I have not had the opportunity of investigating closer the kinetics of the enzyme reaction. It may be that the reaction is of zero order; but the values of K_0 according to the formula $K_0 = \frac{x}{t}$ differ little from the values of K_1 and the increase of enzyme activity, expressed as K_0, is the same as that expressed as K_1. The kinetics of the reaction are being investigated.

Inhibition of Chemi-luminescence of Luminol by means of Oximes

IT is known that oximes with widely different chemical structures are effective reactivators of cholinesterase inhibited by organo-phosphorous compounds (esters of phosphoric or thiophoric acid, insecticides, nerve gases)[1]. The mechanism of this reaction is considered to be due to the chemical interaction of oximes with the free or bound ester of phosphoric acid, which is hydrolysed by the oxime[2], and is not available for the inhibition of the cholinesterase. It is known that organo-phosphorous compounds catalyse the luminol reaction causing an intensive chemi-luminescence of luminol (3-aminophthalylhydrazide) in alkaline medium in the presence of sodium perborate as oxygen donor[3].

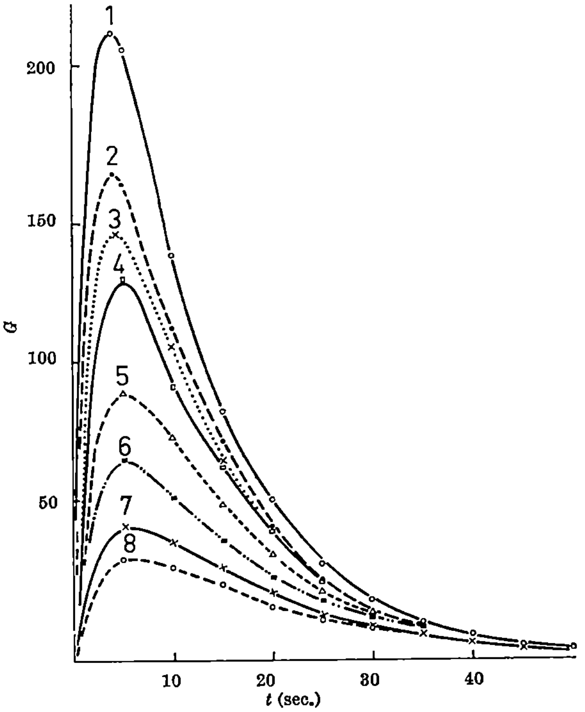

Fig. 1

In view of this evidence it was felt that the oximes will inhibit the luminol reaction catalysed by organophosphorous compounds or other suitable catalyst, that is, hæmoproteins or other complexes with iron. This type of inhibition would proceed with a mechanism analogous to the reactivation of cholinesterase as mentioned here.

Quantitative investigations of the chemi-luminescence of luminol have proved that a large number of oximes inhibits the luminol reaction catalysed by organo-phosphorous compounds or complexes of iron. The inhibition caused a significant decrease of the chemi-luminescence. The results of a series of experiments are presented (Fig. 1). G represents the relative intensity of chemi-luminescence in relation to the reaction time t. Curve 1 records the results obtained

Table 1

Hæmoglobin (gm. per cent) / Inhibitor	2×10^{-5}	4×10^{-5}	1×10^{-4}
	$i_{1/2}\,M$		
2-Hydroxyiminopropane	$5{\cdot}90 \times 10^{-2}$		$6{\cdot}10 \times 10^{-2}$
4-Hydroxyimino-methyl-N-methyl-pyridinium iodide	$1{\cdot}34 \times 10^{-2}$		$1{\cdot}54 \times 10^{-2}$
2-Hydroxyiminobutanone-(3)	$1{\cdot}11 \times 10^{-2}$	$1{\cdot}25 \times 10^{-2}$	$1{\cdot}40 \times 10^{-2}$
2-Hydroxyimino-methyl-N-methyl-pyridinium iodide	$2{\cdot}25 \times 10^{-3}$	$2{\cdot}50 \times 10^{-3}$	$3{\cdot}25 \times 10^{-3}$
N,N′-Tetramethylene-*bis*(4-hydroxyimino-methylpyridium bromide)	$6{\cdot}90 \times 10^{-4}$	$7{\cdot}10 \times 10^{-4}$	$7{\cdot}80 \times 10^{-4}$

without oxime, while curves 2–8 illustrate the effect of increasing concentrations of pyridine-4-aldoxime methiodide. In all these experiments the luminol reaction was catalysed by hæmoglobin. The results clearly demonstrate that the maximal intensities of chemi-luminescence as well as the total amount of light (area under each curve) were reduced when increasing amounts of oxime were used.

Essentially the same results were obtained when other oximes (inhibitors) and other catalysts of luminol reaction were applied. Table 1 shows molar concentrations of various oximes which decrease the chemi-luminescence to a value of 50 per cent at various concentrations of hæmoglobin. It is evident that oximes inhibit the luminol reaction effectively.

These findings present not only an additional proof for the mechanism of reactivation of cholinesterase with oximes, but also the method described in this communication provides a means for a simple evaluation of oximes as reactivators of cholinesterase.

Further details of these and other experiments on related subjects will be published elsewhere.

Inactivation and Reactivation of Chymotrypsin

In previous work on the immediate effects of acylation of trypsin it was shown[1] that the enzyme can be obtained in a fully inactive form by acylation with various anhydrides at *p*H 8–9, and that partial instantaneous reactivation can be effected by treatment with alkaline hydroxylamine[2].

In an extension of this work it was found that chymotrypsin behaves similarly to trypsin on acylation at higher *p*H values, complete inactivation occurring at *p*H 8. Even though a reactivation was observed on incubation, it was almost negligible in the course of 2 hr. The acylations were carried out using an automatic titration unit (Polarad Electronics Corp.), at various constant *p*H values. In Table 1 are recorded the percentages of inactivation and reactivation in terms of proteolytic activity obtained on acetylation at 0–5° C. at different *p*H values, whereby 60 equiv. of acetic anhydride were used per mole of enzyme. The activity was assayed at *p*H 7·8, using the usual hæmoglobin substrate. Any inactivation rapidly reversed at that *p*H [3,4] could accordingly not have been observed.

Table 1. Inactivation of Chymotrypsin at Different *p*H Values

Time (min.)	Activity (per cent) 5	6	7	8
0	100	100	100	100
8	65	56	31	0
20	64	58	35	0
120	67	60	38	0

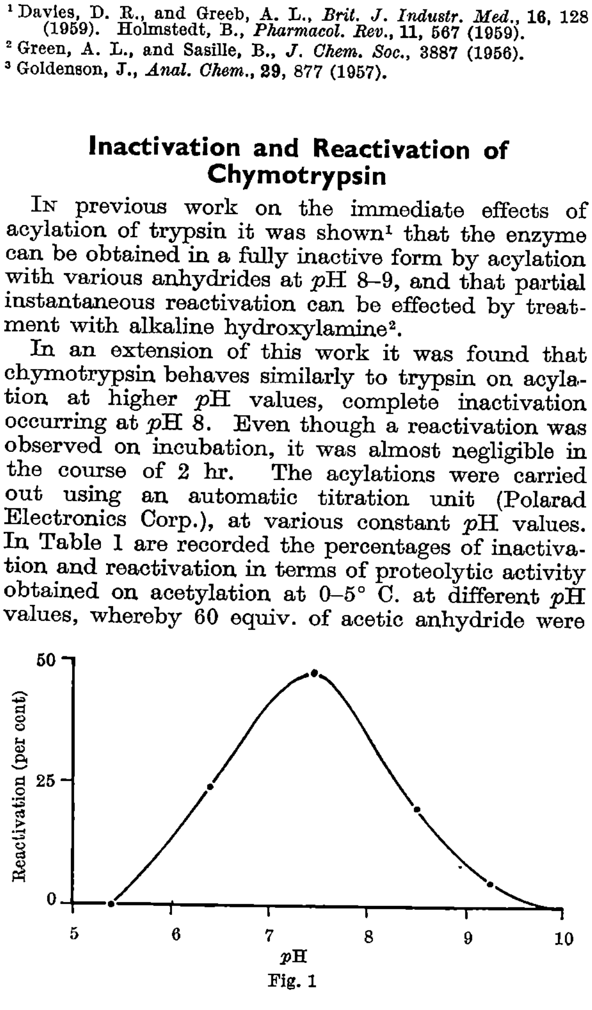

Fig. 1

Butyric and propionic anhydrides gave similar results. As observed in the case of trypsin, citraconic anhydride gave rise to an inactivation amounting to only about 50 per cent.

Even though the spontaneous reactivation of acetylchymotrypsin is much slower than in the case of acetyltrypsin, an instantaneous reactivation was obtained on treatment with hydroxylamine. In Fig. 1 is shown the extent of reactivation recorded at various *p*H values on treatment of the inactivated chymotrypsin for a period of 8 min. with 4 equiv. of hydroxylamine per equivalent of anhydride added. It can be seen that maximum reactivation takes place in the region of *p*H 7·4–7·8. The reactivation bears a striking resemblance to the reaction of inactive acetyltrypsin with hydroxylamine[2] except that the *p*H optimum of reactivation is shifted to lower *p*H values by about one *p*H unit.

The inactive monoacetyl chymotrypsin obtained by other investigators[3,4] was reactive with hydroxylamine in the region of *p*H 5–6. In reaction with nitrophenylacetate there is also a great similarity between trypsin and chymotrypsin and the monoacetyl enzymes obtained were more stable at *p*H 5–6, easily undergoing hydrolysis at *p*H 7–8. However, in the case of the inactive acetyl derivatives obtained at *p*H 8, it was found that they were more stable at *p*H 7–8 than at *p*H 5–6. The hypothesis[2] that there are two susceptible sites in the active centre of trypsin, acetylated at *p*H 5 and *p*H 8 respectively, appears to be supported in the case of chymotrypsin. The small deviations in the *p*H optima of reactivation with hydroxylamine could be attributed to secondary differences between the two enzymes.

Activity of Glutamic Acid Decarboxylase in Insect Nerve Tissue

As compared with the nerve tissue of mammals, that of insects is known to be particularly rich in acetylcholinesterase[1] and in choline-acetylase[2]. On the other hand, nothing has been reported so far about the occurrence in insects of another enzyme which, in mammals, is characteristic of nerve tissue, namely, glutamic acid decarboxylase. Its reaction product, γ-aminobutyric acid, has been recently found in the free state in bee nerve tissue, in amounts of the same order, on the basis of fresh weight, as in mammalian nerve tissue (Carta, S., and Frontali, N., unpublished work).

Homogenates of worker honeybee brains (including the optic lobes) have been used for determinations of glutamic acid decarboxylase by the manometric technique[3], and compared with mouse brain homogenates. The average values thus obtained were 690 µl. carbon dioxide/hr./gm. of fresh tissue for the mouse and 1,250 for the bee.

Further work on the characteristics of the glutamic acid decarboxylase of bee nerve tissue was made difficult by the large amounts of material necessary for each determination, even when Warburg microvessels were used (at least 0·1 gm. tissue, which is approximately 80 brains). For this reason a different method of assay of glutamic acid decarboxylase was worked out and found suitable for activity determinations on as little as 2–4 mgm. of tissue. It was based on the use of uniformly labelled glutamic acid-^{14}C as substrate, and on the measurement of the radioactivity of the γ-aminobutyric acid produced.

Preliminary experiments showed (1) that labelled glutamic acid, incubated with a bee brain homogenate under the same conditions as the Warburg determination and subjected to two-dimensional paper chromatography for amino-acids, gave rise to one new radioactive spot, having the R_F values of γ-aminobutyric acid ; (2) that this spot, eluted and co-chromatographed with authentic inert γ-aminobutyric acid, could be superimposed perfectly on the resulting ninhydrin spot.

The general procedure was as follows, each determination being run in duplicate. Small test-tubes (30 mm. × 6 mm.) were pre-cooled in ground ice with 20 µl. of the reaction mixture, which was prepared in such a way as to give a final concentration of 0·0005 *M* pyridoxal phosphate and 0·025 *M* L-glutamic acid ; each test-tube contained 0·2 µc. of labelled L-glutamic acid (from the Radiochemical Centre, Amersham, England). Next, 20 µl. of bee brain homogenate 1 : 5 in 0·1 *M* phosphate buffer *p*H 6·4 were added. The test-tubes were closed with rubber stoppers, and by means of two injection needles (inlet and outlet) through the stopper, pure nitrogen was passed through them for 2 min.; the needles were quickly removed at the end of the gassing period. At zero time the test-tubes were immersed in a water-bath at 38°, except for one which was immediately deproteinized to serve as a control. After incubation for 20 min., the test-tubes were chilled on ice, opened and immediately deproteinized with 100 µl. of 99 per cent ethanol. After centrifugation, measured aliquots of the supernatant fluids were subjected to one-dimensional ascending paper chromatography in phenol/water/concentrated ammonia (77·5 : 21·5 : 1). The radioactivity was measured by the quantitative paper radiochromatographic technique described by Beloff-Chain *et al.*[4]. The results obtained by this method were found to agree with those obtained by the manometric technique.

The above method was then applied to the study of some properties of the glutamic acid decarboxylase of bee brain. Enzyme activity, as a function of coenzyme concentration and of time, was examined. The results of these experiments showed that (1), the optimal concentration of pyridoxal phosphate is between 4 × 10^{-4} and 10^{-3} *M*, (2) the time/activity curve is almost linear during the first 20 min.

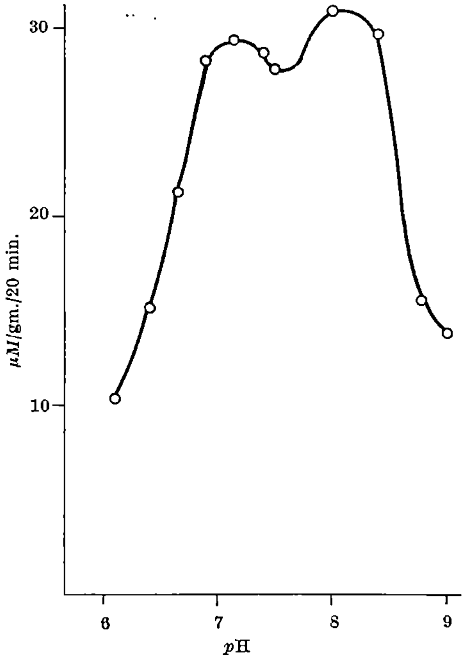

Fig. 1. Production of γ-aminobutyric acid from glutamic acid as a function of *p*H

Enzyme activity as a function of *p*H was then investigated. A homogenate of bee brain in 0·1 *M* potassium chloride was incubated with the usual reaction mixture and with a phosphate-borate buffer[5] ranging from *p*H 6 to 9. The amounts of γ-aminobutyric acid formed were determined in the usual way and plotted against the *p*H. The resulting curve showed two peaks of maximum γ-aminobutyric acid production at *p*H values around 7·2 and 8·0 respectively (Fig. 1). The second peak could correspond to an alternative route of γ-aminobutyric acid production, in which glutamic acid decarboxylase is not involved. If this can be shown to be true, the method described in this communication should be used as a measure of glutamic acid decarboxylase activity only between certain limits of *p*H.

Enzymic Conversion of Tetrahydrofolic Acid to Folinic Acid by Plant Protein

ENZYMIC synthesis of folinic acid (CF) has been investigated in a variety of cells of both bacterial and animal origin[1–7].

The purpose of this communication is to report the isolation and partial characterization of a crude protein fraction from a plant source demonstrating 'transformylase' activity in converting tetrahydrofolic acid to folinic acid.

Folic acid was obtained from the Nutritional Biochemical Corporation, Cleveland, Ohio. Formylfolic acid (FF) was prepared by the method of Shive *et al.*[8]. Identity was verified by the method of Weislogel *et al.*[9]. Tetrahydrofolic acid (THF) was prepared by an adaptation of the method of O'Dell *et al.*[10]. Folinic acid-SF was supplied through the courtesy of Eli Lily Co., Indianapolis, Indiana. Mustard leaves were obtained locally.

Turnip or mustard leaves (2·5 kgm.) were homogenized in a Waring blendor in a v/v solution of acetone chilled with dry ice and phosphate buffer (0·05 M) at *p*H 7·2. The homogenate was collected by filtration; acetone was removed by vacuum distillation, and the residue was extracted with 500 ml. phosphate buffer at *p*H 7·2.

The volume was reduced to 250 ml. by pervaporation and the debris which accumulated was removed by centrifugation. Protein was precipitated by adding ammonium sulphate (42 gm./100 ml. volume).

Further purification of the fraction was accomplished by suspending the protein precipitate in a minimum of buffer, clarifying the suspension by centrifugation, and by discarding the small amount of insoluble precipitate. The centrifugate was reprecipitated with ammonium sulphate at the same saturation-level as used in the precipitation of the crude fraction. The precipitate was collected by centrifugation, dissolved in buffer, and dialysed against potassium phosphate buffer until no precipitate occurred on the addition of 0·1 M barium chloride to 5 ml. of the buffer bath. The protein was dissolved in phosphate buffer to give 63·20 μgm. in 0·2 ml. of solution. Protein determination was by the method of Lowrey[4].

The biosynthesis media contained the following substances: tetrahydrofolic acid, 2 μgm.; glucose, 8 μM; ascorbic acid, 4 μM; sodium formate, 20 μM; $MgSO_4.7H_2O$, 1 μM; diphosphopyridine nucleotide, 0·05 μM; adenosine triphosphate, 0·05 μM; protein fraction, 0·1 mgm.; buffer (potassium phosphate *p*H 7·0), 1·0 ml. in a total volume of 4·0 ml.

After 4 hr. incubation at 30° C., the biosynthesis samples were clarified by centrifugation, the *p*H adjusted to 7, and assayed for folinic acid activity with *P. cerevisiae* (*ATCC* 8081) in a manner described previously[2]. Samples containing no protein, as well as samples containing only protein, gave no stimulation of growth of *P. cerevisiae*, when assayed under identical conditions as the biosynthesis samples.

Substrate specificity for this enzyme was estimated by using formyl-THF, THF, and folic acid. THF gave the best conversion to folinic acid, although, in each case, the yield of folinic acid was low, due, perhaps, in part to substrate instability, unacceptability of D-forms of the stereoisomers, and the impure condition of the enzyme. In determinations of the effects of *p*H, and temperature, 2 μgm. of THF per 5 ml. of biosynthesis medium were employed, and the amount of protein was reduced from 0·1 mgm. to 0·03 mgm.

Because of the observed influence of both temperature and *p*H (Table 1), as well as the absence of activity of folinic acid, when no protein was present, it can be said that the conversion of THF to folinic acid by this plant protein is enzymic.

These results show the normally observed inactivation of enzyme activity at extremes of, as well as the optimum, activity within the mid-range of *p*H and temperature, which compares favourably with observations of effects of *p*H and temperature on similar enzymic conversions of folic acid derivatives to folinic acid in both bacteria and animals.

Table 1. EFFECT OF *p*H AND TEMPERATURE ON THE ENZYMIC CONVERSION OF TETRAHYDROFOLIC ACID TO FOLINIC ACID

*p*H	Conversion (per cent)*	Temperature (° C.)	Conversion (per cent)†
4·0	0	10	0
6·0	12	25	8
8·0	12	37	16
10·0	2	90	0

* Percentage conversion of tetrahydrofolic acid to folinic acid per mgm. of crude protein at 30° C. Incubation time, 4 hr. Assays for folinic acid activity were for 18 hr. at 37° C.

† *p*H 7.

Further purification of the active fraction is necessary in order to make a thorough study of the properties of this enzyme.

Regulation of Pyrogallol Oxidations by Alcohols and Sugars

PREVIOUSLY, it has been shown that the catalytic activity of Fe(III) or peroxidase can be enhanced by a variety of colloidal substances including deoxyribonucleic acid[1], celluloses[2], and starch[3]. Other investigations[4–6] have demonstrated the macromolecular activation or modification of a number of oxidative or hydrolytic systems. Such observations direct attention to the role of environmental factors other than those usually encountered *in vitro* in biochemical reactions.

Although investigations of this type are not common, they possess potentially great significance as demonstrations of the regulatory effects to be expected when reactions take place within the colloidal system of the cell. Such investigations also stimulate interest in still other kinds of model environments which might possess biological counterparts. We may consider, for example, the properties of the solvent medium wherein reactions occur, such as dielectric constant and viscosity. Using alcohols and polyhydric substances such as glycerol and sugars as solvent-modifying solutes, it has been found that the autoxidation and enzymic oxidation of pyrogallol can indeed be regulated by solvent properties.

In these experiments, the oxidation of 0·05 M pyrogallol at 25° C. in 0·01 M phosphate buffer, *p*H 5·6, was followed photometrically at 425 mμ. In the higher alcohol concentrations, buffer salts were omitted.

It is known that the autoxidation-rate declines in pure alcohols with increasing length of carbon chain[7],

Table 1. Effects of Alcohols on Autoxidation of Pyrogallol
(*a*) Simple alcohols

Concentration (*M*)	Methanol	Ethanol	*n*-Propanol	Glycerol
0*	100	100	100	100
0·01	—	198	350	226
0·1	175	200	330	253
1·0	152	233	330	253
5·0	101	110	153	150
10·0	—	64	14	33

(*b*) Sugars

	Sucrose	Glucose
0†	100	100
0·01	88	88
0·1	119	94
0·5	123	—
1·0	105	100
2·0	32	65
5·0	—	16

*, In water, the control absorbance at 425 mμ after 24 hr. is 0·152; †, in water, the control absorbance at 425 mμ after 50 hr. is 0·450.

but the enhancement of oxidation by dilute aqueous alcohols was unexpected (Table 1*a*). Several alcohols at 0·01–5 *M* cause pronounced acceleration and at concentrations in excess of 5 *M* pronounced inhibition.

Glycerol acts like the monohydric alcohols; however, other polyhydric substances, sucrose and glucose (Table 1*b*), affect only the inhibition of autoxidation when supplied at concentrations greater than 1 *M*. On the basis of their molar concentrations, the sugars are more inhibitory than the simple alcohols. At 5 *M*, the simpler alcohols are inactive or stimulatory whereas both sucrose and glucose inhibit autoxidation at the 2 *M* concentration.

The theoretical and mechanistic bases for these effects will be discussed elsewhere, and it will suffice here to mention several possibilities in outline: (1) Enhancement by dilute ethanol and *n*-propanol may involve participation in radical chain transfer reactions. (2) Inhibition by more concentrated alcohols may involve reduced ionization of pyrogallol in media of much lower dielectric constant than water. Inhibition by ethanol and *n*-propanol specifically may also involve their radical chain-stopping (anti-oxidant) activities. (3) Enhancement by methanol and glycerol does not now lend itself to explanation. (4) Inhibition by the sugars and glycerol may involve the retarding effect of viscous media. The non-inhibitory concentrations give solutions of 5 centipoise or less, whereas the viscosities of inhibitory solutions range upwards from 50 centipoise.

Some of the effects described are not restricted to homogeneous autoxidation systems, but may be extended to enzymic peroxidations as well. Using the peroxidase system described in previous work[3], we have found that methanol at concentrations of 5 *M* or less accelerates pyrogallol oxidations appreciably (Table 2).

Table 2. Effects of Methanol on Enzymic Peroxidation of Pyrogallol

Methanol *M*	Yield of purpurogallin (mμmoles/l.) at 0·5	1·0	1·5	2·0	2·5	3·0 min.
0	11·3	23·7	33·8	38·8	44·0	48·1
2·5	8·1	19·4	34·4	47·5	62·5	66·0
3·75	5·6	14·4	27·5	39·4	53·8	62·5
5·0	4·1	9·1	17·2	28·1	40·6	53·1
7·5	2·8	5·6	9·4	13·8	18·8	25·0
10·0	1·9	4·7	7·8	11·0	14·7	18·5
12·5	1·0	1·3	2·0	2·8	3·5	4·4

At concentrations of 0·5 *M*, sugar solutions inhibited enzymic oxidation by 15–20 per cent, but at 5 *M* the inhibition was increased to about 50 per cent. Hence, methanol and the sugars exert similar effects on the slow reaction between pyrogallol and oxygen and the fast catalytic reaction between pyrogallol and hydrogen peroxide. The biological significance of these results lies mainly in the principle illustrated, namely, that modifications in aqueous reaction media brought about by the presence of various simple hydroxylic substances can influence the rates of oxidative reactions.

Such effects could give rise to differences in rate among cells or parts of cells without requiring corresponding differences in catalyst or reactant concentrations.

PHYSIOLOGY

Importance of Magnesium in the Control of Plasma Calcium in the Calf

It has been known for many years[1] that when calves are fed for an abnormally long time on milk only they usually, sooner or later, become hypomagnesæmic. In my experiments, four out of sixteen calves fed to about five months of age or more on milk without supplementary vitamin D showed neither hypomagnesæmia nor hypocalcæmia while the remainder became hypomagnesæmic. Of the latter, all but one showed a fall in plasma calcium more or less closely correlated with the fall in plasma magnesium. An example is shown in Fig. 1 and other examples have been reported previously[2]. My work has shown fairly clearly that the hypomagnesæmia is due to magnesium deficiency resulting from a decrease in the ability of the calves to absorb dietary magnesium as they get older[3], but the reason for the hypocalcæmia is less clear.

I have found that the efficiency of calcium utilization as well as that of magnesium decreases as the calves get older and that addition of a large amount of vitamin D (70,000 I.U./day) to the diet both improves calcium utilization and rapidly restores plasma calcium to normal[2]. Smaller amounts of vitamin D (300–7,000 I.U./day) have also been found to be beneficial, but less so than the larger amount[2].

Table 1

Age (weeks)	Diet	Magnesium intake (gm./day)	Calcium intake (gm./day)	Calcium net absorption (per cent of intake ± S.E.)	Calcium excretion in urine (per cent of intake ± S.E.)	Plasma magnesium (mgm./100 ml.) mean and range	Plasma calcium (mgm./100 ml.) mean and range
16½–18½	Milk	0·69	7·1	61 ± 6	0·35 ± 0·09	1·35 (0·91–2·08)	8·5 (7·4–10·6)
19½–21½	Milk + $MgCl_2$	4·0	7·1	42 ± 11	1·44 ± 0·74	2·34 (1·94–2·54)	10·8 (9·4–12·7)

Mean results from 8-day balance experiments with 4 calves kept out of direct sunlight and previously fed only on milk (4·4–6·15 l./day with supplementary iron, copper and manganese) throughout their lives. Immediately after the first balance period, the magnesium chloride supplement was added to the diet and subcutaneous magnesium sulphate injections (1 gm. magnesium/day) were given for 7 days. The second balance period was started 4–6 days after the injections ceased. General procedure and analysis was carried out as described previously (ref. 2).

Now milk, particularly winter milk which is what the calves here received, contains little vitamin D (about 10 I.U./l.); but, although it is clear that the vitamin D level must be low for the hypocalcæmia to occur, there are a number of facts which suggest that vitamin D-deficiency is not its sole cause. First, calves on vitamin D-deficient but otherwise normal diets do not readily show hypocalcæmia, even though they may suffer bone changes and show clinical signs of rickets[4]. Secondly, deficiency of vitamin D cannot explain the correlation between falls in plasma magnesium and plasma calcium; plasma magnesium and magnesium absorption are not appreciably influenced by vitamin D (ref. 2). Finally, I have now found that a restoration of plasma calcium to nearly normal levels occurred in four milk-fed hypomagnesæmic and hypocalcæmic calves when the plasma magnesium was restored by giving oral and parenteral supplements of magnesium even though no supplementary vitamin D was given. An example of the effect is shown in Fig. 1. With different animals an increased amount of magnesium in the diet has been variously reported as improving[5], inhibiting[6] and having no marked effect on[7] net calcium absorption. To examine the possibility of an improvement in calcium utilization accompanying magnesium supplementation in the above calves, calcium balances were carried out just before daily magnesium supplementation was started and again about ten days after it was started. Mean results are shown in Table 1.

Although the results do not prove that magnesium supplementation rather than a simple age effect caused the decrease in net calcium absorption, it is nevertheless true that an increase in plasma calcium occurred in all these calves in the face of decreased net absorption of dietary calcium and, as a mean effect, increased urine excretion of calcium (in some calves urine calcium increased markedly, in others it remained unchanged). It seems very probable, therefore, that the homeostatic mechanism for calcium, presumably that controlling the bone/extracellular fluid equilibrium, is sensitive, under certain conditions, to the magnesium status of the calf as reflected by the level of plasma magnesium. I have no evidence as to whether magnesium exerts its effect directly on the bone/extracellular fluid equilibrium or otherwise, but bearing in mind that, in the young calf, the plasma magnesium-level reflects the magnesium content of the bone[8], it can be seen that the idea of a direct effect is in accordance with the *in vitro* findings of W. F. Neuman and his co-workers[9] that the presence of certain foreign ions, including magnesium, increases the effective solubility of bone hydroxy-apatite crystals.

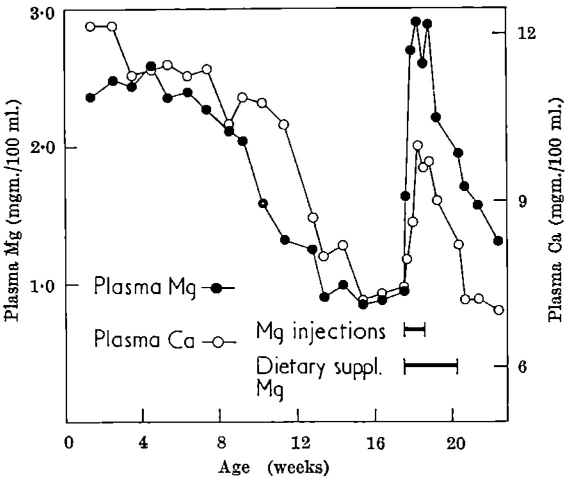

Fig. 1. Calf fed only on milk (4·4–6·15 l./day with supplementary iron, copper and manganese) and kept out of direct sunlight. Dietary supplement of 28 gm. $MgCl_2.6H_2O$/day and daily subcutaneous injections of 10 gm. $MgSO_4.7H_2O$ given as shown. During injection period blood samples were taken 24 hr. after an injection

Analogous considerations might account for the frequent occurrence of hypocalcæmia in adult bovines developing clinical hypomagnesæmia.

Although some tendency for low plasma calcium to be associated with low plasma magnesium has occasionally been observed by other workers with milk-fed calves (particularly by Parr[10], who often found hypocalcæmia in hypomagnesæmic calves even though they received about 430 I.U. vitamin D/day and who also found that the hypocalcæmia was alleviated by supplementary magnesium), the close correlation which I observed has not been reported previously. Its absence is often explicable by differences in vitamin D intake and might also sometimes be explained by differences in the amounts and types of foreign solid matter eaten by the calves in addition to their milk. Calves kept on fluid diets for longer than a few weeks develop a very strong desire for solid material to chew and will often eat almost anything. The calves used here were kept muzzled and were bedded on wood shavings, but they still usually succeeded in eating a small amount of these shavings.

Synaptic Transmission in Neurosecretory Cells

SINCE Scharrer's discovery[1], many types of neurosecretory systems have been investigated histologically in almost all kinds of animals. However, there is no publication dealing with them in terms of electrical activities except the brief note of Potter and Loewenstein[2], in which the presence of synapses between neurosecretory cells and other nerve cells was only indirectly indicated.

The caudal neurosecretory system of the eel, *Anguilla japonica*, was found by Enami[3]. In this system the cells are fairly large and clearly seen in fresh material under a dissecting microscope. This fact enabled us to use the micro-electrode technique, and the results obtained with this method clearly showed the synaptic transmission at the cell-bodies as well as other characteristics of the nervous function.

After the caudal spinal column of approximately 20 vertebræ was isolated from the eel, the spinal cord was exposed at several vertebræ including the tail end. This preparation was fixed with 'Vaseline' on a paraffin block in a leucite chamber, and the exposed spinal cord was washed sufficiently with the teleost Ringer. Intracellular records from the cell-bodies of these neurosecretory cells showed resting membrane potentials of 50–60 mV. inside negative and overshoots of 10 mV. or more in action potentials. The duration of the action potential was 8–10 msec. at 14–17° C. and the threshold membrane depolarization was around 12–13 mV. A long lasting outward current pulse resulted in repetitive discharge of spikes, at the end of which an under-shoot of the membrane potential was clearly seen (Fig. 1). These characteristics are very similar to those of the spinal ganglion cells of the frog[4].

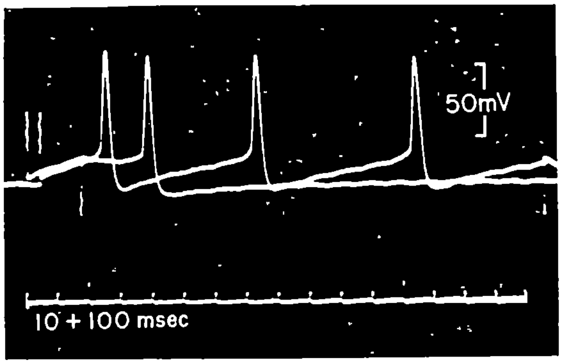

Fig. 1. Spike potentials of a cell body elicited by outward current pulses. The responses to brief and long pulses are superimposed

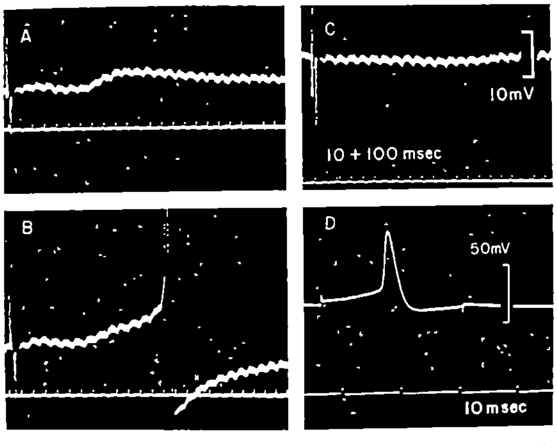

Fig. 2. An experiment showing synaptic transmission. *A*, synaptic potential evoked by a rather weak stimulation of a spinal cord at an anterior part; *B*, synaptic potential followed by a spike in the case of a stronger stimulation; *C*, after treatment of the spinal cord with potassium chloride in a region between the stimulating and recording positions. The stimulus was much stronger than in *B*; *D*, after *C*, the cell was directly stimulated by an outward current

When the spinal cord was stimulated at an anterior segment, a slow potential change was recorded from the neurosecretory cell-body after some delay (Fig. 2*A*). If the stimulus was strong enough, a spike potential was initiated at the summit of the slow potential (Fig. 2*B*). After this spinal cord was treated with potassium chloride in a region between the stimulating and recording positions, no electrical changes were evoked by a stimulus several times as strong as that which could elicit the spike potential (Fig 2*C*). Even then, this cell responded to a stimulus directly applied to the cell-body (Fig. 2*D*). Thus, the slow potential mentioned above may be safely regarded as the synaptic potential, which is also supported by the fact that the temporal summation was clearly observed. The conduction velocity of the fastest fibres in the presynoptic nerve was about 0·6 m./sec. at 15° C., but that of the neuro-secretory cell could not be measured owing to the short length of the axone, though antidromic stimulation of it was possible.

From the results of the present work it may be concluded that the neurosecretory cells have complete nervous characteristics, and that the activities of these cells are controlled by axones from higher nervous centres, though their locations are quite open for further investigations.

Changes in Blood Serotonin during Exposure to Cold

SEROTONIN is a recently discovered biogenic amine which can be extracted from brain, blood, and other organs, and which is active on a wide variety of systems when injected into the animal[1]. Gathering of knowledge concerning serotonin's physiological importance has been slowed by an inability to observe fluctuations in its concentration in brain and other tissues, in a wide variety of circumstances simulating physiological mobilization[2–4]. A single exception to this is the observation of a release of serotonin into the bowel, controlled by, and in turn modifying, peristaltic activity[5]. Also, more recently, Toh has reported rat brain serotonin to drop following exposure to cold associated with drop in body-temperature of 36–30° C. (ref. 3).

Below I present further data relating serotonin to natural mechanisms, reporting serotonin perturbations in the rat's blood during a short-term exposure to cold, not associated with change in body temperature. 200-gm. female rats were taken from an atmosphere varying from 75° to 80° F. and placed on a metal surface in a cold room maintained at 36–38° F. Animals of exps. 1–3 were injected with 50 mgm./kgm. sodium heparin intraperitoneally to facilitate blood collection, 30–40 min. before the beginning of exposure to cold. At specified intervals, of 15 sec.–20 min. duration, they were decapitated, and bled into cold siliconized test-tubes containing 1 drop of heparin. Adapting a method of Weissbach[6], 0·5 c.c. rat blood was pipetted into 7 c.c. of cold distilled water and lysed, and 2·5 c.c. of a 5 per cent zinc sulphate solution was added with shaking. The tubes were then neutralized with the appropriate quantity of sodium hydroxide, shaken again and centrifuged. The supernatants were treated in one of three ways: they were analysed for 5-hydroxyindole content by direct fluorimetry[6], or extracted and analysed specifically for 5-hydroxytryptamine (serotonin) by combination of the zinc sulphate protein precipitation[6] with the Bogdanski extraction procedure[7], one very close to Weissbach's extraction method, or, they were split, and both direct and extraction analyses carried out on the same sample. The fluorimetric readings of samples and recoveries were performed on a Farrand spectrophotofluorimeter. Samples were found to have emission and absorption spectra identical with processed serotonin.

Table 1. EFFECT OF COLD EXPOSURE ON WHOLE BLOOD SEROTONIN

Exp.	No. of samples	Duration cold exposure	Whole-blood γ/c.c. 5-hydroxyindole		*P*
			Direct method	Extraction method (serotonin)	
1 Rat (heparin)	5	0 min.	0·94 ± 0·24	0·43 ± 0·09	< 0·01
	4	5–7 ,,	1·77 ± 0·20	1·08 ± 0·22	
	4	9–11 ,,	1·63 ± 0·33	1·08 ± 0·17	
	4	20 ,,	1·44 ± 0·50	0·72 ± 0·23	
2 Rat (heparin)	16	0 min.	0·95 ± 0·21	—	< 0·001
	18	15–75 sec.	1·39 ± 0·24	—	
	8	2 min.	1·40 ± 0·34	—	
	8	4 ,,	1·09 ± 0·26	—	
	5	6 ,,	1·01 ± 0·12	—	
	5	11 ,,	0·94 ± 0·28	—	
3 Rat (heparin)	3	0 min.	1·95 ± 0·67	1·77 ± 0·88	—
4 Rat (no heparin)	10	0 min.	—	1·52 ± 0·46	< 0·01
	10	5–9 ,,	—	2·20 ± 0·49	
5 Rabbit	7	0 min.		3·29 ± 0·86	—
Human	7	0 ,,	—	0·12 ± 0·06	
Rat	8	0 ,,	—	1·41 ± 0·29	

The results are described in Table 1. Exp. 1 depicts increases in blood 5-hydroxyindole and serotonin that are approximately equivalent, about 0·7γ serotonin/c.c. whole blood. This elevation begins falling away between the 11th and 20th minute. Exp. 2 examines the same phenomenon by the direct method only. In this experiment the rise and fall of blood 5-hydroxyindole follows a more rapid time course. Exps. 3 and 4, performed a month later, demonstrate an equivalent cold-induced serotonin elevation in animals not injected with heparin. In these experiments, the normal values are seen to be somewhat high in comparison with the values obtained in other experiments for the rat[8,9]. In contrast, as shown in Exp. 5, human and rabbit bloods analysed simultaneously with rat samples gave serotonin titres similar to those obtained by other methods[6,8–11]. No other laboratories report whole-blood analyses for the rat, all blood serotonin values for rats reported to date being derived by calculation from analysis of platelets or platelet-rich plasma[6,8–11]. Thus the somewhat higher normal values we observe remain to be explained: they may reflect a seasonal variation, an inefficiency of methods for gathering platelets in the rat, or, possibly, the existence of a non-platelet source of blood serotonin in this species.

In contrast to Toh's observations[3], it is important to note that the alterations we have observed could not have been provoked by a non-specific lowering of body temperature. Rectal temperatures were not significantly altered in rats exposed to cold for 30 min.

The question of the source of the increase in blood serotonin and the relation of this observation to a local and general increased serotonin metabolism are under investigation at present. We speculate that the perturbations in serotonin concentration observed indicate serotonin participation in cardiovascular and/or metabolic adjustments to cold.

Note added in proof. In recent experiments employing blood drawn by cardiac puncture a cold-induced increase in plasma serotonin was not observed.

Effect of Sodium Fluoride on Calcium Metabolism of Human Beings

ALTHOUGH bones of human subjects become abnormally dense after several years of industrial exposure to fluorides[1,2], no work on the effect of fluoride on calcium balance of human beings has been carried out. Roholm[1] and others[2] have shown that the severity of skeletal changes is correlated approximately with the extent and duration of exposure to fluoride: moderate exposure resulting in increased density of otherwise grossly normal bone, but prolonged heavy exposure resulting in marked changes, including periosteal bone-formation and calcification of ligaments and tendons. How such complex skeletal effects are brought about is unknown; however, the microscopic appearance of depressed or absent osteoclastic activity in bones of moderately affected human beings[1] suggests that relatively low doses of fluoride may somehow depress resorption of bone.

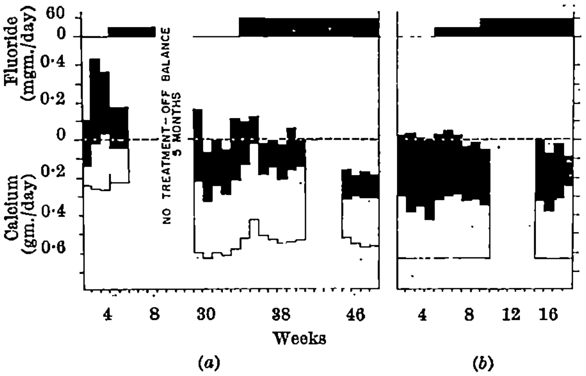

Fig. 1. Calcium balances of a patient with widespread and active Paget's disease (*a*) and of a patient with inactive post-menopausal osteoporosis (*b*). Data are plotted after Albright with intake down and urinary above fæcal calcium

Because of the demonstrated skeletal effect of fluoride in human beings, and because of the relatively benign nature, even of advanced fluorosis[1], it is possible that fluoride could be of use in treatment of diseases where skeletal mass is reduced, the rate of bone resorption accelerated, or both. This work was carried out to determine whether or not metabolic effects, particularly retention of calcium, could be observed during treatment of human beings with sodium fluoride. Six patients with osteoporosis and one with Paget's disease were given carefully measured diets which contained approximately constant amounts of calcium, phosphorus and nitrogen. After a preliminary period of at least one week, stools and urine were collected and balance measurements carried out. Control observations were made, usually for three weeks, after which the patients were given sodium fluoride orally in divided doses (all other treatments remaining unchanged). In early work small doses of fluoride were used and treatment was given for only a few weeks. As it was found that the medication was well tolerated, and that effects observed were seen only after several weeks, the dose was increased to 60 mgm. fluoride a day and duration of treatment extended to 14 or more weeks.

Changes in balance of calcium (the analysis[3] for calcium was unaffected by addition of sodium fluoride) of a subject with widespread and progressive Paget's disease are illustrated by Fig. 1*a*. The decreased rate of excretion of calcium in urine and the calcium retention were most marked late in the investigation, and did not appear to have become maximal during the period of observation. Fig. 1*b* shows similar but less-striking results from study of a post-menopausal patient with minimal X-ray evidence of osteoporosis. Other subjects with osteoporosis also responded by positive change in calcium balance and decreased rate of excretion of calcium in urine. (In one, with osteoporosis secondary to treatment of rheumatoid arthritis with prednisone, urinary calcium excretion fell from 204–240 mgm. per day to 24–68 mgm. per day from the twelfth to the fifteenth week of treatment. This was accompanied by increase of about 80 mgm. a day of fæcal calcium; the intake remaining constant.)

Other significant changes were, in several osteoporotic patients, increased alkaline phosphatase activity in plasma, from normal pre-treatment values to 16–38 King–Armstrong units per 100 ml., decreased rate of excretion of citrate and accelerated excretion of acid mucopolysaccharides in urine. No significant alteration occurred, during treatment of any patient, of concentration in plasma of calcium, phosphorus or citrate. No change in X-ray appearance of the skeleton or abnormality of hæmatological, renal or hepatic function could be measured. The only evidence of possible untoward effect was that, during the period of treatment, two of the seven subjects developed sub-acromial bursitis.

Although these results do not show whether or not fluoride will be useful in treatment of human subjects, they do demonstrate profound effects of fluoride ion on calcium metabolism of patients with several skeletal diseases.

PHARMACOLOGY

Effect of Serotonin on Absorption and Distribution of Calcium-45 in the Rat

CERTAIN pharmacological effects of serotonin might be related to its action on the permeability of cell membranes to various ions. It has been shown that serotonin inhibits the pigment effusion, sodium uptake and potassium efflux from slices of red beetroots *in vitro*[1]. The loss of potassium from erythrocytes in cold storage is reduced by serotonin[2]. An increase of the efflux of sodium and potassium from the isolated skin of a frog was also shown in the presence of serotonin[3]. This latter effect was not considered to be the result of non-specific damage of the cell membranes, because the permeability to Evans blue or sucrose was not affected by serotonin[3]. It is, however, well known that serotonin exerts a marked effect on the capillary permeability in rats[4–6]. Following a different approach, Woolley has proposed that there is an interaction between serotonin and calcium in isolated organs on the basis that serotonin no longer stimulates the uterus in the presence of a calcium-chelating agent[7]. This finding was interpreted as an effect of serotonin in facilitating the penetration of calcium into the cells[8]. On the other hand, calcium seems to be an important factor for serotonin release during the antigen–antibody reaction[9,10].

These results prompted us to investigate a possible role of serotonin in the absorption and distribution of calcium. Experiments have been carried out *in vitro* on the everted intestinal sac of the rat, according to the method of Wilson and Wiseman[11]. Serotonin (5-hydroxytryptamine creatinine sulphate) at a concentration of 20 μgm./ml. increased the absorption of calcium-45 (after 15, 30 or 60 min. of incubation), while acetylcholine (20 μgm./ml.) had no effect. Creatinine sulphate (20 μgm./ml.) was also ineffective. Serotonin retained its effect when the everted intestinal sac was incubated at 5° C. Some of the results are summarized in Table 1.

Table 1. EFFECT OF SEROTONIN AND ACETYLCHOLINE ON CALCIUM-45 ABSORPTION FROM THE EVERTED INTESTINAL SAC AFTER 30 MIN. OF INCUBATION

Substance added	Per cent of calcium-45 absorbed*	Significance (P)
None	$4 \cdot 14 \pm 0 \cdot 09$	—
Serotonin 10	$5 \cdot 49 \pm 0 \cdot 16$	$< 0 \cdot 01$
Acetylcholine 10	$3 \cdot 45 \pm 0 \cdot 06$	$= 0 \cdot 01$
None	$4 \cdot 26 \pm 0 \cdot 11$	—
Serotonin 20	$8 \cdot 05 \pm 0 \cdot 13$	$< 0 \cdot 01$
Acetylcholine 20	$3 \cdot 67 \pm 0 \cdot 10$	$> 0 \cdot 05$

*Each value is the mean of 8 determinations.

The everted intestinal sac (10 cm.) was suspended in 5 ml. of medium containing: NaCl 0·9 per cent (100), KCl 1·15 per cent (4), KH_2PO_4 2·11 per cent (1), buffer phosphate at *p*H 7·4 (10), glucose 0·3 per cent in the final solution. 1 ml. of the same medium was introduced inside the sac. $^{45}CaCl_2$ was added to the outside medium at the dose of 0·4 µc./ml. (specific activity 2·5 µc./mgm. calcium). The flasks were incubated in O_2 at 37° C. in a Warburg apparatus at 96 oscillations/min.

The values represent the percentage of the added radioactivity recovered 'inside' the sac.

The effect of serotonin does not seem to be related to the contraction of the intestine, because acetylcholine at the same concentration is ineffective. Serotonin also increased the penetration of calcium into human cancer cells (strain *Af*(*H.Ep*2))[12] cultivated *in vitro*, as shown in this laboratory by autoradiography (A. Leonardi and R. Vertua, unpublished observations).

Further experiments were carried out to see if the serotonin effect also occurs *in vivo*. Male Sprague Dawley rats, 150 gm. weight, were fasted for 6 hr. and then given both serotonin and calcium, simultaneously, by various routes. The animals were killed at different intervals of time afterwards.

Samples of liver (3 gm.), brain (1 gm.), washed small intestine (2·5 gm.) and blood (1 ml.) were combusted for 12 hr. at 200° C. and for an additional 24 hr. at 700° C.[13]. The ashes were dissolved in 2 *N* hydrochloric acid and mixed with 6·45 mgm. of calcium chloride as carrier. Ammonium oxalate, 4 per cent, was added in excess and then neutralized with ammonia, 25 per cent. When calcium oxalate was completely precipitated (after 4 hr.) it was centrifuged and washed several times with ammonia, 2 per cent, and distilled water. The sample was then plated and the radioactivity was measured using a thin mica end-window Geiger counter.

Table 2. EFFECT OF SEROTONIN ON DISTRIBUTION OF CALCIUM-45

Serotonin mgm./kgm.	hr. between calcium uptake and killing	c.p.m./mgm. calcium			
		Blood	Small intestine	Liver	Brain
—	2	1,023	1,878	1,362	321
25 oral	2	1,230	3,529	1,935	376
—	4	1,153	2,075	703	326
25 oral	4	1,213	2,397	1,120	344
—	1	2,240	9,432	1,519	191
10 i.p.	1	3,824	30,114	1,948	212
—	2	1,572	3,848	1,143	260
10 i.p.	2	2,974	17,816	3,349	390
—	4	1,405	2,730	1,170	378
10 i.p.	4	1,822	5,227	1,903	380

$^{45}CaCl_2$ (specific activity 2·5 µc./mgm. calcium) was given by oral route at the dose of 150 µc./kgm.

It is evident from Table 2 that serotonin increases the absorption of calcium from the intestinal tract. In other experiments not reported in detail, the distribution of calcium-45 after intravenous administration was not greatly affected by serotonin. For this reason, it is likely that the increase of calcium in liver, when calcium was given orally, should probably be related to the increased absorption of calcium from the intestine.

The pharmacological implications of these observations are now under investigation.

Potentiation of Epinephrine Action

THE following experimental results have been reported by our colleagues on the potentiation of epinephrine action by various substances, clarifying part of its mechanism: (1) The potentiation of epinephrine action on vasoconstriction by certain amino-acids was attributed to a reaction in which the oxidized form of epinephrine gave rise to the oxidative de-amination of amino-acids and was reduced by the generated hydrogen[1,2]. (2) The epinephrine potentiation in the presence of histidine resulted from its combination with cupric ion in the tissues, which was considered as one of the oxidizing catalysts of epinephrine[3].

On the other hand, it is generally accepted that there exist some kinds of enzymes which attack epinephrine in living organisms. To investigate the influence of the so-called epinephrine-potentiating substances such as cocaine, ephedrine and catechol-derivatives on these enzymes, O-methyl transferase[4] especially has caught our interest. We have carried out a series of experiments to evaluate the epinephrine potentiation which is attributable to the inhibition of monoamine oxidase and O-methyl transferase by these substances. The following results have been obtained: (1) The inhibitory strength of monoamine oxidase inhibitors such as cocaine, ephedrine, procaine, marsilid and methylene blue *in vitro* did not parallel the degree of epinephrine-potentiating action upon vasoconstriction[5]. (2) Cocaine, ephedrine and procaine manifested no influence on O-methyl transferase activity. Pyrogallol, gallic acid, catechol, some catechol-derivatives and flavonoids proved to be the substrates of O-methyl transferase, and these substances, when co-existing with epinephrine, competitively inhibited the metanephrine formation (Table 1). (3) The epinephrine potentiation by hydroquinone[6] was observed to have no relation to the change in the activity of O-methyl transferase, but it seemed more likely that the reduction of Fe^{+++}-protein followed by the increment of Fe^{++}-protein, a probable constituent of epinephrine receptor[7,8], was the main cause.

Table 1. INHIBITION OF VARIOUS SUBSTANCES ON METANEPHRINE FORMATION

Substance	Dose (μmole)	Metanephrine formed (μmole)
Control	—	$4 \cdot 7 \times 10^{-2}$
Cocaine	2·0	$4 \cdot 8 \times 10^{-2}$
Ephedrine	2·0	$4 \cdot 2 \times 10^{-3}$
Procaine	2·0	$4 \cdot 8 \times 10^{-2}$
Catechol	0·5	$1 \cdot 3 \times 10^{-2}$
Protocatechu aldehyde	0·5	0
Protocatechuic acid	0·5	$0 \cdot 7 \times 10^{-2}$
3,4-dihydroxy phenylacetic acid	0·5	$2 \cdot 1 \times 10^{-2}$
Hydroquinone*	0·5	$4 \cdot 9 \times 10^{-2}$
Gentisic acid*	0·5	$4 \cdot 9 \times 10^{-2}$
Pyrogallol	0·5	0
Gallic acid	0·5	0
Phloroglucin	0·5	$4 \cdot 2 \times 10^{-2}$
Rutin	0·5	0
Quercetin	0·5	0

Each substance was added to the following mixture and incubated at 37·5° C. for 30 min. under anaerobic conditions: epinephrine, 0·5 μmole; magnesium chloride, 20 μmole; *S*-adenosylmethionine, 0·5 μmole; *tris*-buffer, 100 μmole; crude enzyme (the soluble supernatant fraction obtained from rat liver prepared by Axelrod's method (ref. 4)), 0·6 ml. and water to make a final volume of 2·0 ml. Metanephrine formed was estimated by Pisano's method. Each value is the mean of three experiments. The standard deviation was within 10 per cent.

* Gentisic acid and hydroquinone proved to be the substrates of O-methyl transferase in this reaction mixture.

Table 2. INHIBITION OF THE UPTAKE OF EPINEPHRINE BY COCAINE, EPHEDRINE AND PROCAINE

	Dose (final concentration, *M*)	Epinephrine uptake (μgm./mgm. of dry weight)
Control (0° C.)	—	0·35
Control (37·5° C.)	—	3·30
Ephedrine	10^{-3}	0·48
Cocaine	10^{-3}	0·51
	10^{-4}	0·73
	4×10^{-5}	0·99
	4×10^{-6}	1·99
	4×10^{-7}	2·64
Procaine	4×10^{-5}	2·79
	4×10^{-6}	3·06
	4×10^{-7}	3·10

Platelets were suspended in 2·5 ml. of the phosphate saline containing 200 μgm. of epinephrine and different concentrations of each substance. The mixture was incubated at 37·5° C. for 90 min. Values given represent the mean of three experiments. The standard deviation was within 10 per cent.

Recently, problems on the uptake of catecholamines by some tissues and release from them have become of interest to us. It is a matter of course that the mechanism of epinephrine potentiation should also be analysed from this point of view. Accordingly, we have tried a model experiment on the uptake and release of epinephrine using rabbit blood platelets, and obtained the following result: The uptake of epinephrine by rabbit blood platelets was inhibited by cocaine, ephedrine and procaine (Table 2), and their inhibitory strength was parallel with their potentiation degree of epinephrine action.

From our experimental results mentioned here, we have classified the mechanism of the epinephrine potentiation by various substances as follows:

(1) Competitive inhibition on the enzymes, especially *O*-methyl transferase in inactivating epinephrine. (Pyrogallol, gallic acid, catechol, some catechol-derivatives, and flavonoids.)

(2) Inhibition of the uptake of epinephrine by blood platelets, blood cells and other tissues. (Cocaine, ephedrine and procaine.)

(3) Chelation with cupric ion that is a catalytic agent of the oxidation of the phenol ring of epinephrine. (Histidine, alanine, glycine, methionine and phenylalanine.)

(4) Acceleration of 'oxidation-reduction' turn-over of epinephrine. (Certain amino-acids and ascorbic acid.)

(5) Reduction of Fe^{+++}-protein to Fe^{++}-protein, a probable constituent of epinephrine receptor. (Hydroquinone, cysteine, ascorbic acid and glutathione.)

We wish to express our sincere thanks to Prof. T. Suzuki, Kyoto University, for his donation of S-adenosyl methionine.

HÆMATOLOGY

Action of Influenza Viruses, Receptor-destroying Enzyme and Proteases on Blood Group Agglutinogen M^g

THE ability of influenza viruses and receptor-destroying enzyme from *Vibrio cholerae* to inactivate human erythrocyte agglutinogens *M* and *N* was first noted in this Laboratory[1] and afterwards independently in Finland[2]. Lu^a and Lu^b agglutinogens are also inactivated by influenza viruses but not by the receptor-destroying enzyme[3]. None of 17 additional human blood group agglutinogens—including *S* and *s* which are considered to be products of genes very closely linked to the *M* and *N* genes—was destroyed by these agents[1,3]. On the other hand, the inactivation of a number of erythrocyte agglutinogens including *M* and *N* by papain, trypsin and other enzymes has been known for a considerable time[4–6].

Recently a new blood-group factor, M^g, was described by Allen, Corcoran, Kenton and Breare[7] and thought to be the product of a gene allelomorphous to the *M* and *N* genes. It was of interest, therefore, to investigate the effect of enzymically active agents on this 'new' erythrocyte agglutinogen.

B, MM^g and *O*, NM^g erythrocytes (Paul and John Gilfeather respectively; cf. ref. 7) and serum (lot No. SM^g-50) containing saline agglutinating anti-M^g antibodies of a titre of 1 : 8 were obtained with the co-operation of Dr. F. H. Allen, jun., from the Blood Grouping Laboratory, Boston. A saline-agglutinating anti-M^g serum with a titre of 1 : 1–1 : 2, found in this Hospital's blood bank, was also used. The erythrocytes were washed with 0·85 per cent saline and treated with purified influenza viruses (Melbourne and Swine S_{15} of type *A* and Lee of type *B*), with the receptor-destroying enzyme from *Vibrio cholerae*, papain and trypsin as previously described[1,8] and also with three times the amount of virus used in earlier experiments. Physiological saline buffered with 0·005 *M* veronal to *p*H 7·4 and containing a trace of calcium chloride was substituted for the phosphate buffer used earlier.

Table 1. Effect of Influenza Viruses and Receptior-Destroying Enzyme on Human Erythrocyte Agglutinogens (Gilfeather)

Serum		Agglutinogen tested for	Erythrocytes	Serum unabsorbed: Native	Serum unabsorbed: Neuraminidase-treated	Serum absorbed with neuraminidase-treated erythrocytes: Native	Serum absorbed with neuraminidase-treated erythrocytes: Neuraminidase-treated
				Agglutination of erythrocytes*			
anti-*M*	Human (*J.C.*)	*M*	Paul Gilfeather *B*, MM^g	8	4–8	8	<1
	Human (*SJM*–1)	*M*		4–8	1	4	<1
anti-M^g	Human (SM^g–50)	M^g		4–8	16	<1	<1
anti-*B*	Human (*P.W.*)	*B*		64	128	<1	<1
anti-*N*	Human (Ar. donated by Dr. H. Gershowitz)	*N*	John Gilfeather *O*, NM^g	32	16	16–32	<1
	Vicia graminea (*J.C.* 60)	*N*		16	<1	32	<1
anti-M^g	Human (SM^g–50)	M^g		8	32	<1	<1
	Human (2111/61)	M^g		1–2	4–8		
anti-*H*(*O*)	Eel (*E.D.*60)	*O*		128	512	2	8

* Expressed as reciprocal of serum dilution.

The results with influenza viruses and the receptor-destroying enzyme were similar and are listed in Table 1. These results show clearly that treatment of Gilfeather erythrocytes with influenza viruses or the receptor-destroying enzyme inactivates *M* and *N* but not M^g (columns 3 and 4, Table 1). The *B* and *H*(*O*) antigens of these erythrocytes, serving as controls, are not inactivated by this treatment. Lack of inactivation of the M^g, *B* and *O*(*H*) agglutinogens is demonstrated by the increased titres of the respective agglutinins (columns 3 and 4, Table 1) against neuraminidase-treated erythrocytes as compared to the titres against native erythrocytes. The increase in agglutinin titre against non-inactivated agglutinogens appears to be due to the additive effect of the titre against the native receptor plus *T*-agglutination against the *T* antigen unmasked by neuraminidase (cf. ref. 1). The *T* agglutinin alone, however, is not sufficiently strong to prevent the demonstration of the inactivation of the *M* and *N* factors as the agglutinin titre does not rise but decreases (column 4, Table 1). To eliminate the interfering action of *T* agglutinins, erythrocytes treated with the same enzymically active agent were used for both absorption of sera and titration of agglutinins. A comparison of the data in the third and fifth columns of Table 1 shows that absorption with neuraminidase-treated erythrocytes removes anti-M^g, anti-*B* and anti-*H*(*O*) agglutinins but not anti-*M* and anti-*N* agglutinins. The anti-*M* and anti-*N* titres against untreated erythrocytes are the same before and after absorption. This indicates inactivation of *M* and *N* agglutinogens of the neuraminidase-treated red cells, as does also a comparison of the last two columns of Table 1, where the titres are listed after removal of anti-*T* agglutinins. Trypsin and papain, however, completely inactivate the M^g receptor. Untreated *M* and *N* erythrocytes removed their respective antibodies in one absorption with one volume of packed erythrocytes.

There was no demonstrable change of the agglutinogens under investigation when they were incubated with either uninoculated allantoic fluid, boiled influenza viruses or autoclaved enzymes.

B, MM^g and *O*, NM^g erythrocytes were agglutinated by influenza viruses as were other human erythrocytes and also became inagglutinable by the virus to which they had been exposed extensively.

The lack of inactivation of agglutinogen M^g by influenza viruses and the receptor-destroying enzyme, in contrast to that of antigens *M* and *N*, is unexpected in view of the assumed close serological and genetical relation of blood group receptors *M*, *N* and M^g (ref. 7). It recalls, however, similar observations for the *ABO* blood-group system where certain enzyme preparations will inactivate all three blood group antigens while others will affect only one. It is believed that influenza viruses possess only one enzyme, neuraminidase[9]. Based on the activity of influenza viruses, it has been assumed that derivatives of neuraminic acid (sialic acids) are closely involved in the specificity of blood group agglutinogens *M* and *N*[1,2,10,11]. While this assumption is reasonable, it is obvious from the data presented here that if M^g is indeed an allele to *M* and *N*, it is unlikely that identical sialic acids in identical linkages are involved in the specificities of the products of the allelomorphic genes *M*, M^g and *N*. Influenza virus enzyme may thus be a more sensitive tool than papain and trypsin in the investigation of fine structural differences of products of blood-group genes of the *MNS* system.

The Diego Factor in a Puerto Rican Family: a Case of Anti-Diego$_a$ in Monozygotic Twins

The Diego blood factor exists in many South American people having a substantial Indian admixture[1]. The following family is the first reported from Puerto Rico.

Mrs. P. F. M., a Puerto Rican woman, age thirty-seven, residing in New York City, delivered premature, monozygotic, female twins, with positive direct Coombs tests. She had four full-term spontaneous deliveries by her first husband (Di^{a-}), and two early abortions and one miscarriage before the twins, by her second husband (Di^{a+}). On close observation for seven weeks neither twin developed any signs or symptoms of hæmolytic disease of the new-born other than minimal hepato-splenomegaly.

Serological investigations revealed the father to be group O, R_1R_1, Di^{a+}, both twins to be group A, Di^{a+}, R_1R_2, the mother, group A_2, R_2r and Di^{a-}. The hæmolytic antibody formed by iso-immunization was anti-Diego, detected by an indirect Coombs test with a titre 1 : 32. Investigation of the father's family revealed the Diego factor in his aunt, paternal grandmother, and great uncle, all natives of Puerto Rico and exhibiting Indian features. The Di^{a+} cases were typed for ABO, D, C, c, E, e, V, $MNSs$, P, K, k, Fy^a, Le^a, Le^b, Jk^a, Jk^b, Lu^a, Lu^b, Js^a, Yt^a, Kp^b, Wr^a, Vel, Good, Santos, Gerbich, without adding new information pertaining to the independent segregation of Di^a gene.

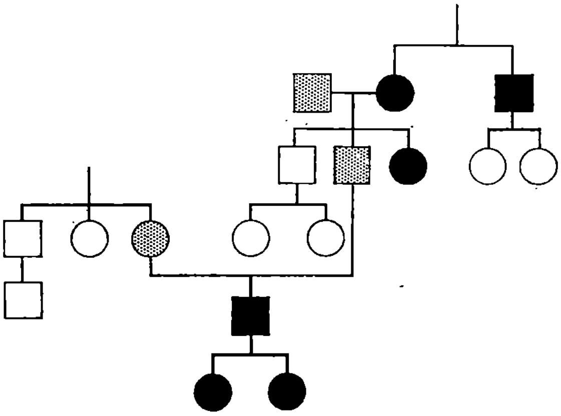

Fig. 1. The anti-Diego (Di^a) factor in four generations of a Puerto Rican family. Black, Di^a-positive; shaded, not tested, deceased; open, Di^a-negative

This anti-Diego is the first reported which caused no symptoms in the infants who provoked immunization. The prematurity of these twins should have heightened their susceptibility to hæmolytic disease. Perhaps several near-term gestations are necessary to stimulate formation of a clinically apparent antibody, a state analogous to Rh disease in non-transfused patients.

The original case (Diego), a Venezuelan child, who died of hæmolytic disease of the new-born, was fourth in birth order with two older Di^{a+} siblings[2]. The second case (W.O.J.) was third in birth order with non-fatal hæmolytic disease (Levine, P., personal communication). The third case was fifth in birth order (Mart) and died from severe erythroblastosis fœtalis[3].

Table 1

	Mother	Twins	Father
Group	A_2	A	O
Rh D	+	+	+
C	−	+	+
E	+	+	−
d	+	−	−
c	+	+	−
e	+	+	+
	cDE/cde	*DCeDcE*	*DCe/DCe*
WR^a	−	−	−
Kp^a	−	−	−
Kp^b	+	+	+
He	−	−	−
Di^a	−	+	+

The true hazard of sensitization to Di^a is not known. Layrisse stated that in 50 cases of Di^a incompatible matings no antibodies were formed in an unspecified number of gestations[4].

Among Chinese with a 2·5 per cent incidence of Di^a, hæmolytic disease is very rare. Clinically, anti-Diego has not yet proved to be of great significance. Nevertheless, the present case demonstrates that undetected antibodies to Di^a will be missed if not sought for. Our rule of an antiglobulin test on premature infants revealed iso-immunization. Among populations with a high incidence of the Diego factor, it remains a potential cause of fœtal wastage.

PATHOLOGY

Effects of Carrageenin on Serum Lipids and Atherosclerosis in Rabbits

IN recent years considerable interest has developed regarding an important role of aortic mucopolysaccharides with advancing age. On the other hand, a number of reports have dealt with the activities of heparin and other sulphated polysaccharides to clear visible lipæmia and also to retard arteriosclerotic process in arterial walls.

The object of this communication is to report a hitherto undescribed effect of carrageenin, a natural sulphated polysaccharide, obtained from seaweeds, in suppressing hyperlipæmia and atherosclerosis in cholesterol-fed rabbits. Carrageenin obtained from *Chondrus ocellatus* contained 11·86 per cent sulphur. It showed a specific optical rotation of +28°. The experiment was performed as follows :

A number of male albino rabbits were all fed a daily diet consisting of bean-curd-mash and cholesterol at the rate of 100 mgm. per kgm. body-weight during the course of 18 weeks. The animals were divided into two groups : (1) cholesterol-fed plus carrageenin-injected group consisted of 21 rabbits ; (2) a control group of 19 rabbits fed cholesterol only. The animals of the treated group received individually a daily intravenous injection of 5 mgm. of carrageenin per kgm. body-weight. At 2-week intervals, serum lipids such as total lipid[1], total and esterified cholesterol[2], phospholipid[3], β/α lipoprotein ratio[4] and turbidity of the serum were measured. At the end of the experiment, all rabbits were killed, and the atheromatous lesions in the aorta were examined macroscopically and microscopically.

The results of the experiment revealed that carrageenin possesses suppressing effects on the rise of

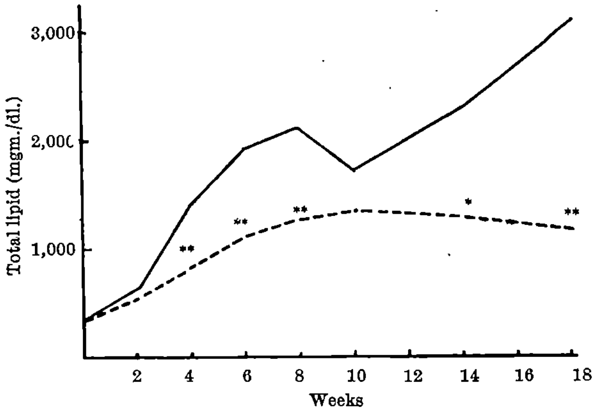

Fig. 1. Mean serum total lipid in cholesterol-fed plus carrageenin-injected group and in cholesterol-fed control group. – – –, Carrageenin; ——, control. *, significant; **, highly significant

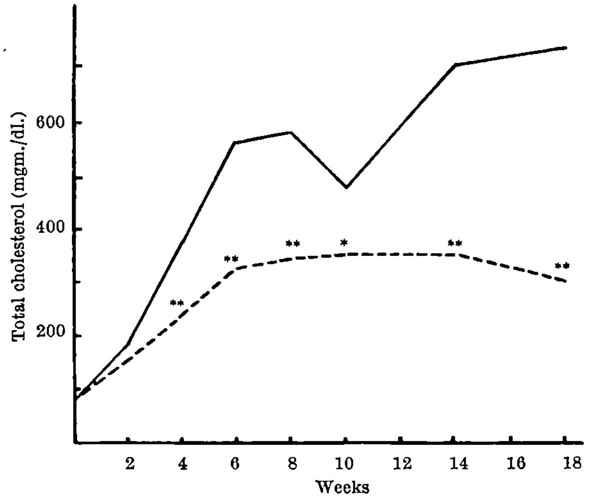

Fig. 2. Effect of carrageenin on serum total cholesterol. – – –, carrageenin; ——, control. *, significant; **, highly significant

serum lipids in cholesterol-fed rabbits. Figs. 1 and 2 show that the mean serum total lipid and total cholesterol-levels in the treated group showed less increase compared with the control after 4 weeks following the beginning of injection of carrageenin, and significant differences between the two groups were noticed during the experiment except for the early period. In addition, remarkable differences of the mean levels in cholesterol and phospholipid ratio, β/α lipoprotein ratio and serum turbidity in both the groups were noticed. Lipæmia-clearing activity was shown following the administration of carrageenin. However, carrageenin failed to prove its anticoagulant activity, at least at the dosage of 5 mgm. per kgm. body-weight, according to the Lee and White method.

The visual grading of severity of atheromatous lesions, as determined by their distribution, size and number, was shown to be almost parallel to the concentration of the serum lipids. The microscopic findings, according to several stainings, supported the result in the gross findings that the grade of severity of atheromatous lesions was much less in the carrageenin-treated rabbits than in the controls.

T. Mori[5] reported that carrageenin consists of 30–40 per cent D-galactose and 20–30 per cent sulphate. The finding[6] that the subcutaneous injection of carrageenin into animals stimulated the formation of new connective tissue will support the presumption that carrageenin plays a part in promoting the repair of atheromatous lesions, when an adequate supply of it is provided.

Grateful acknowledgment is made to Prof. Y. Oshima for his kind advice while carrying out this investigation.

Immunofluorescence of Pleuropneumonia-like Organisms isolated from Tissue Cell Cultures

It has been established that continuous tissue cell cultures are commonly contaminated with pleuropneumonia-like organisms and/or *L*-forms of bacteria[1-5]. These results have encouraged investigators to search for reasonably simple methods for the detection of these agents, especially in relation to studies for their elimination. Of methods proposed for their detection, cultivation and isolation have proved most successful[6]. With the advent of the fluorescent antibody technique as a rapid method for the identification of micro-organisms, it seemed to us that this procedure might be useful as a means of detecting contamination of pleuropneumonia-like organisms in tissue cell cultures. The feasibility of this technique is presented here.

Strain *HEp* 2, isolated from the human epidermoid carcinoma of skin (Fjelde) cell line, was propagated in primary rabbit kidney cells for the preparation of antigen for antibody production in New Zealand white rabbits. The antiserum was conjugated with fluorescein *iso*thiocyanate in the manner described by Marshall *et al.*[7]. Lissamine rhodamine *RB* 200 was conjugated to normal bovine serum albumin and added to the labelled antiserum as a counterstain[8].

Contaminated continuous cell cultures and infected primary rabbit kidney cells grown on cover-slips in Leighton tubes were fixed in buffered formalin, washed, and then stained with the fluorescein-conjugated antiserum for 1 hr. at 37° C. in a wet chamber.

The strains of pleuropneumonia-like organisms, isolated from the cell lines mentioned here, were also grown on membrane disks (Millipore Filter Corporation, Bedford, Massachusetts) placed on PPLO agar medium[6]. Impressions were made by transferring colonies from disks to microscopic slides, air drying, and staining them for 15 min. at room temperature. The stained preparations were examined with a Zeiss fluorescence microscope, using the Osram *HBO* 200 light source, the *BG*-12 exciter filter, and the *GG*4-*OG*4 barrier filter.

Fluorescein-conjugated antiserum reacted specifically with the homologous pleuropneumonia strain (Fig. 1) when tested with the original contaminated cell lines, infected primary cells, and colonial impressions. Strains isolated from five other continuous cell cultures maintained regularly in both of our laboratories reacted in the same manner. These cultures were HeLa—human carcinoma of cervix (Gey); HA—human amnion (Fogh and Lund); HI—human embryonic intestine (Henle); KB—human carcinoma of nasopharynx (Eagle); and conjunctiva—human adult (Chang). Non-infected primary tissue cell cultures previously found by cultural methods to be free of pleuropneumonia-like organisms gave no staining reactions. These preliminary findings suggest that tissue culture strains of these organisms may have similar antigenic structures. Since the organisms were isolated from tissue cultures used in different laboratories, the chance of contamination from a common source could probably be ruled out. On the other hand, it may be that tissue cell cultures favour the selection and development of the same or related strains of the organism.

Heterologous human urethral strain 07 (Dr. Paul Smith, Philadelphia) and strain Campo (Dr. Louis Dienes, Boston) did not react with the *HEp* 2 tissue culture antiserum. This indicates that there are differences between the antigenic structures of these strains. The reaction and non-reaction of colonial impressions of *HEp* 2 and 07, tested with the antiserum simultaneously on the same slide, are shown in Fig. 2.

In order to establish the specificity of the fluorescein-conjugated antiserum of the organisms, 24 bacterial and mycotic organisms were tested. None reacted. Included were strains from the genera *Salmonella, Shigella, Proteus, Staphylococcus, Streptococcus, Diplococcus, Corynebacterium, Pseudomonas, Serratia, Escherichia, Aerobacter,* and *Cryptococcus.*

Antisera to vaccinia, adenovirus type 7, herpes simplex, and infectious canine hepatitis viruses prepared in rabbits and conjugated with fluorescein *iso*thiocyanate did not react with the six continuous cell cultures contaminated with the organism.

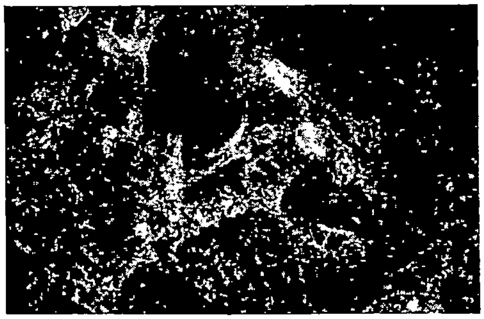

Fig. 1. Monkey (*a*) and rabbit (*b*) kidney tissue cells infected with pleuropneumonial strain *HEp* 2 stained with labelled homologous immune serum. (*a*, × 225; *b*, × 200)

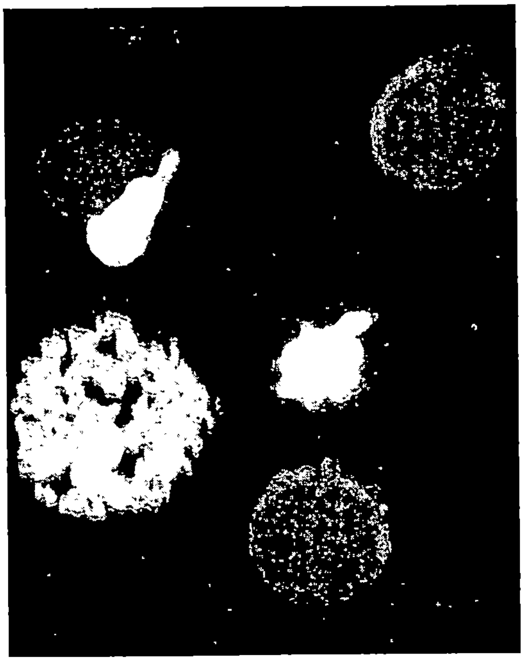

Fig. 2. Impression smears of pleuropneumonial strains *HEp* 2 and 07 stained with labelled *HEp* 2 immune serum. (× 270)

Recent reports indicate that *L*-forms of bacteria rather than pleuropneumonial organisms are the responsible contaminants of cell cultures. Workers in the United States[9] have identified a Gram-negative rod as the bacterial parent, whereas workers in Great Britain[5] have reported a *Corynebacterium.* If the organisms discussed in this communication were in fact *L*-forms of bacteria, then there is reason to suggest that a common bacterium was the source or that the *L*-forms of at least some heterologous bacteria have common antigens.

The staining pattern of fluorescence of pleuropneumonial organisms in tissue cell cultures is similar to the intracytoplasmic granulation pattern consistent with contamination by pleuropneumonial organisms. The fluorescent bodies were found concentrated along the cytoplasmic membrane, in the cytoplasma, and at times along the nuclear membrane. They were not seen within the nucleus.

IMMUNOLOGY

An Immunological Study of a Human Pituitary Interstitial Cell-stimulating Hormone

Several investigators[1–5] have reported recently the production of rabbit antiserum to human urinary gonadotrophins, but no similar data have appeared with respect to human pituitary gonad-stimulating substances. However, an immunochemical investigation in this Laboratory[6] has shown that a highly purified preparation of sheep pituitary interstitial cell-stimulating hormone (ICSH) is a potent antigen. The rabbit antiserum obtained in that work[6] was highly specific for the antigen and was able significantly to counteract its ability to stimulate the ventral prostate in hypophysectomized rats. By the Ouchterlony double diffusion test in agar-gel and the quantitative precipitin technique, the sheep interstitial cell-stimulating hormone was demonstrated to be homogeneous. Moreover, antiserum to sheep interstitial cell-stimulating hormone was capable of neutralizing significantly the interstitial cell-stimulating hormone activity of pituitary extracts from the rat, pig and whale, as well as of purified preparations of human pituitary interstitial cell-stimulating hormone and pregnant mare serum gonadotrophin. Injected antiserum to sheep interstitial cell-stimulating hormone was also shown to cause an inhibition of endogenous activity of the hormone in normal rats. The results of similar investigations on the antigenicity of human pituitary interstitial cell-stimulating hormone are reported here.

The antigen, human interstitial cell-stimulating hormone, was prepared from human pituitaries by the procedure previously described[7]. Two albino rabbits weighing initially 2·6–2·8 kgm. were immunized with a total dose of 8 mgm. of the purified hormone per rabbit, according to the following schedule. Each rabbit was given three injections, consisting of 1·5 mgm. of human interstitial cell-stimulating hormone in Freund's adjuvant (complete), once weekly for three consecutive weeks, was allowed to rest for ten days, and was then given a fourth injection of 1·5 mgm. of human interstitial cell-stimulating hormone. The animals were once again rested for ten days, during which time they were usually test-bled from the marginal ear vein. Finally, animals were bled by heart puncture ten days after a booster shot of 2 mgm. of human interstitial cell-stimulating hormone in saline. The pooled sera showed the presence of contaminating antibodies to normal human serum proteins and, to a very slight extent, to human growth hormone. These contaminating antibodies were selectively removed by absorption by the addition of small quantities of 1 : 10 diluted normal human serum and a dilute solution of human growth hormone. The agar-gel diffusion test was used to determine whether the absorption was complete. This absorbed serum was used in all subsequent experiments.

The presence in the absorbed antiserum of a precipitating type of antibody specific to human interstitial cell-stimulating hormone was demonstrated by means of the qualitative ring test[8], double diffusion on Ouchterlony agar-gel plates[9], immunoelectrophoresis[10], and on the basis of antihormone activity as measured by the capacity of the antiserum to neutralize the activity of the test material in hypophysectomized male rats[11,12]. The capacity of antiserum to human interstitial cell-stimulating hormone to neutralize the biological activity of human chorionic gonadotrophin (HCG) was also tested in the normal female rat.

In the qualitative precipitin ring test, by layering 0·1 ml. of absorbed antiserum under a solution of antigen, it was possible to detect 1 μgm. of human interstitial cell-stimulating hormone. The single precipitin line which human interstitial cell-stimulating hormone gave with the absorbed antiserum in both agar-gel double diffusion analysis and immunoelectrophoresis demonstrated the homogeneity of the antigen–antibody system. It was further noted that the antiserum cross-reacted with a component (interstitial cell-stimulating hormone) in a saline extract of human pituitary glands, giving a single continuous precipitin band with that formed with purified human interstitial cell-stimulating hormone in the agar-gel double diffusion experiment.

Table 1 presents results concerning the capacity of the human interstitial cell-stimulating hormone antiserum to inhibit or neutralize effectively the activity of human gonadotrophins in hypophysectomized male rats ; a total dose of 1·0 ml. of the antiserum given over a period of 4 days effectively neutralizes the biological activity of human interstitial cell-stimulating hormone and human chorionic gonadotrophin.

In normal female rats, the biological activity of human chorionic gonadotrophin was counteracted by the simultaneous administration of rabbit antiserum to human interstitial cell-stimulating hormone ; when human chorionic gonadotrophin alone was given to a group of 10 rats (21 days of age at onset), a total dose of 40 μgm. administered intraperitoneally over a period of 3 days produced an ovarian weight (mean ± standard error) of 36·2 ± 1·92 mgm., whereas with the same dose of human chorionic gonadotrophin plus a 1-ml. total dose of the antiserum the weight of the ovaries was only 15·5 ± 1·09 mgm. Furthermore, when tested by the Ouchterlony double diffusion technique, human chorionic gonadotrophin cross-reacted with rabbit antiserum to human interstitial cell-stimulating hormone. It can thus be concluded that human interstitial cell-stimulating hormone is a potent antigen and that it should be possible to develop immunochemical assay methods to determine the content of interstitial cell-stimulating hormone in human pituitary gland and in body fluids.

Table 1. Effect of Rabbit Antiserum to Human Interstitial Cell-stimulating Hormone on the Biological Activity of Gonadotrophin Preparations as assayed in Immature Hypophysectomized Male Rats

Group	No. of rats per group	Material assayed	Total dose in 4 days (μgm. + ml.)	Weight of ventral prostate (mgm.)	Statistical comparison of groups
1	9	Uninjected controls	0	7·0 ± 0·14*	
2	15	Human ICSH	8 + 0	18·1 ± 0·49	
3	7	Human ICSH + antiserum	8 + 1	7·5 ± 0·30	2, 3; $P < 0{\cdot}001$†
4	6	HCG	1 + 0	15·5 ± 1·5	
5	5	HCG + antiserum	1 + 1	10·0 ± 0·83	4, 5: $P < 0{\cdot}01$

* Mean ± standard error. † Values calculated according to Fisher's *t*-test.

Occurrence of an *Rh*-like Antigen in Red Cells of the Sheep

Landsteiner and Wiener[1] discovered that the sera of rabbits immunized by the erythrocytes of the rhesus (macacus) monkey would agglutinate those of certain human subjects irrespective of their *ABO* groups. They added, therefore, the *Rh*-antigen to the list of antigens characterizing the human red cells. Some human red cells, therefore, must be assumed to possess a receptor-substance for antibodies which rabbits or still better guinea pigs can form when immunized with rhesus erythrocytes. Later, Wiener and Peters[2] demonstrated the antigenicity of the *Rh*-receptor of human erythrocytes in man, thus establishing the principal cause for erythroblastosis in the new-born.

Apart from the *Rh*-antibody obtained by immunization of guinea pigs with rhesus erythrocytes, there are antibodies formed in women eventually immunized when bearing a fœtus possessing *Rh*-erythrocytes or possibly formed in human males and females following transfusion of blood incompatible with *Rh*.

As is known, *Rh* denotes a group of antigens distinguishable in man and the *Rh*-antigen marked *D* according to Fisher[3] is the most common in man, and human *D*-erythrocytes are also agglutinated by an anti-*Rh* guinea pig immune serum.

Therefore, two anti-*D* sera occur, one the human anti-*D* and the other an animal immune anti-*Rh* serum which can be used as anti-*D*. These sera, however, are different: the human anti-*D* serum contains only human *Rh*-antibodies, for example, anti-*D*, besides other human isohæmagglutinins of the *ABO* and other systems, while the guinea pig immunized with rhesus erythrocytes produces, besides antibodies against the rhesus *D*, those which are able to react with some receptor-substance on human erythrocytes very similar to the rhesus *D*, and when immunized with human *D*-erythrocytes the guinea pig (or rabbit) may produce besides anti-*D* also human species-specific antibodies. The latter may explain the observation[4] that animal anti-*Rh* immune serum can react with human fœtal (*Rh*-) erythrocytes. Thus, there are many differences between the animal and the human anti-*D* sera. But the anti-*D* itself appears to be different in that the rhesus *D* cannot be identical to the human *D*, since rhesus erythrocytes, while able to absorb the anti-*D* antibodies from a guinea pig anti-rhesus erythrocyte immune-serum, cannot absorb the anti-*D* from human anti-*D* serum, which itself can be absorbed easily by human *D*-erythrocytes. Even by washing three times the rhesus erythrocytes sediment which is in 1 : 1 ratio to human anti-*D* serum, we did not succeed in nine cases in decreasing the anti-*D* titre, but to one dilution step only. This failure confirms earlier observations[5] where there was no success in absorbing a guinea pig anti-rhesus erythrocytes immune serum by human *D* red blood cells.

On account of the immunizing effect, however, *D*-antigen must be present in both human and rhesus erythrocytes, but apparently in such a way masked or concealed in the stroma that its presence cannot be proved serologically, but by immunization only. Murray and Clark[6], by immunizing guinea pigs with human *dd*-erythrocytes, are believed to have succeeded in stimulating the formation of anti-*D* antibodies.

In our experiments, boiling in distilled water did not free enough *D* from rhesus erythrocytes to enable the boiled cells completely to absorb human anti-*D* antibody, but, however, to decrease its titre to one or, in some experiments, to two more dilution steps as had been possible in the experiments mentioned by using fresh rhesus red cells. Boiling red cells, however, had proved effectual in demonstrating the presence of *D* antigen in experiments with sheep erythrocytes.

When sheep red cells, suspended in distilled water (not in saline solution), are boiled, they can absorb completely anti-*D* antibodies from both anti-*D* sera from patients as well as from commercial anti-*D* test sera, while human erythrocytes, treated in the same way by boiling, were not able to absorb anti-*D* to a similar extent. A more detailed account of these experiments will be published elsewhere[7]. Here only some details may be mentioned which require further experimental research: (1) Whether the presence of the *D* antigen in the red cells of sheep bears any relation with other blood grouping characteristics in sheep is not ascertained as yet. (2) Why boiling must be done in distilled water instead of saline remains to be shown. (3) The *Rh*-antigen in sheep red cells appears to represent only that portion which is common to both *C* and *D* antigens, since the absorbing power of boiled ovine red cells, investigated so far, does not distinguish between *C* and *D* antibodies. (4) Experiments are in progress to show whether immunization of guinea pigs or rabbits with boiled red cells of the sheep will produce, besides Forssman antibodies, *Rh*-(*D*?)-antibodies.

BIOLOGY

Experimental Evidence for the Mechanism of Photosynthesis

FIVE types of short-timed absorption changes (type 0, 1, 2*a*, 2*b*, 3) have been found in photosynthesis[1]. Type 0 is caused by the formation of chlorophyll-triplet states, and occurs only when conduction of energy is interrupted by altering the arrangement of chlorophyll in the chromatophores. Type 1 is caused by the formation of a chlorophyll-*a* derivative (life-time 3×10^{-5} sec.) and occurs only in the normal arrangement of chlorophyll. For details regarding types 0 and 1, see ref. 1 and especially ref. 2.

The difference spectrum of type 2 absorption change is shown in Fig. 1*a*; it appears in $\leqslant 10^{-5}$ sec. and has a life-time of $\sim 10^{-2}$ sec. Type 2 consists of two processes: type 2*a* (negative peak at ~ 420 mμ) and type 2*b* (negative peak at ~475 mμ and positive peak at ~515 mμ). At −150° C. type 2*b* does not occur; the remaining reaction is type 2*a*. From the appearance at −150° C. it follows that type 2*a* must be caused by one primary product of photosynthesis. From the dependence on wave-length at −150° C., it follows that the primary product is probably an oxidized cytochrome[3].

Type 2*b* change of absorption is caused by a reduction process[4]: $X0 \rightarrow X$. On extracting chloroplasts with petroleum ether, the absorption changes of type 2*b* no longer occur. They reappear on recondensation[3]. As plastoquinone is extracted by petroleum ether[5], $X/X0$ may be identical with plastoquinone. Since plastoquinone has no absorption at 515 and 475 mμ, the absorption changes probably take place indirectly by changing the absorption of other pigments during the redox reaction of $X/X0$ (ref. 1).

Since 1956 it has been known[6] that probably two chlorophyll pigments are involved in photosynthesis (Emerson effect): after Govindjee[6] one chlorophyll *a* (*b* ?) with an absorption maximum at ~ 670 mμ and a second one with a maximum at ~ 680 mμ or at longer wave-lengths. We have tried to find out by which of the two pigments the primary product type 2*a* is produced and what is the function of the other pigment. Exposure at ~ 670 mμ causes excitation of Chl*a*-670 and Chl*a*-680, because of the strong overlapping of the absorption bands of the two pigments. Such an excitation causes the absorption changes of type 2*a* and type 2*b*, as already shown in Fig. 1*a*. Exposure at ~ 710 mμ causes mainly excitation of Chl*a*-680. The changes in absorption thus appearing are illustrated in Fig. 1*b*. Type 2*b* is reduced strongly (dotted line), whereas the absorption changes at ~ 420 mμ (characteristic of type 2*a*) remain unchanged. Moreover, changes in absorption can be observed at ~ 400 mμ and ~ 555 mμ, which, owing to their kinetic behaviour, are to be ascribed to type 2*a* (solid line in Fig. 1*b*). These additional changes cannot be seen in Fig. 1*a*, as they are probably compensated by type 2*b*. From the dependence on wave-length of type 2*a* absorption changes (solid line in Fig. 1*b*), it follows convincingly that type 2*a* in *Chlorella* is caused at least by an oxidation of a cytochrome, probably cytochrome *f*.

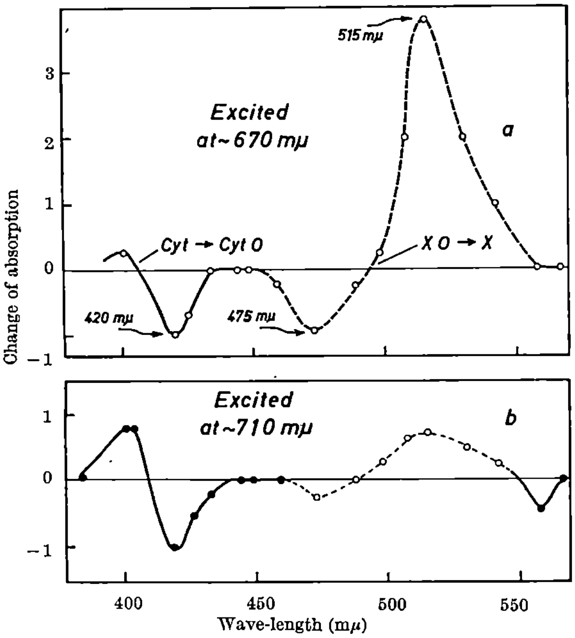

Fig. 1. Changes of absorption caused by illumination of *Chlorella* at two different wave-lengths. Temperature, 20° C.

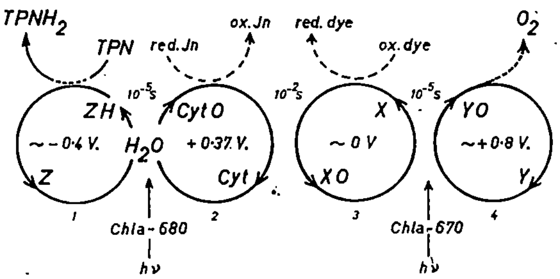

Fig. 2. Reaction pattern of photosynthesis

These results show directly that photosynthesis is triggered by two different photochemical reactions: oxidation of cytochrome by Chl*a*-680 and reduction of $X0$ by Chl*a*-670. The occurrence of two photochemical processes results in a reaction pattern of photosynthesis which differs considerably from previous conceptions. The pattern presumed is shown in Fig. 2. ZH means the reduced form of Z (addition of H or electron); $Y0$, etc., the oxidized form of Y, etc. (loss of electron). The location of water between cycle 1 and 2 is only symbolic; the splitting probably occurs by $Y^+ + 1/2\ H_2O \rightarrow Y + 1/4\ O_2 + H^+$ and $Z^- + H^+ \rightarrow ZH$. Y and Z are chemically not known. The redox potential of cytochrome *f* is + 0·37 V. (ref. 7); that of $X/X0$ has been estimated as ~ 0 V. (ref. 4). The potential of $Y/Y0$ must correspond approximately to that of OH^-/O_2 (~ + 0·8 V.). That of ZH/Z amounts to ~ − 0·4 V., as triphosphopyridine nucleotide[8] and substances with redox potentials up to − 0·4 V. can be reduced by chloroplasts[9]. Thus an energy equivalent of at least ~ 0·8 V. each must be produced by the two primary processes. Phosphorylation[10] very probably occurs by the energy released between cycles 2 and 3. With reduced triphosphopyridine nucleotide and adenosine triphosphate, carbon dioxide can be reduced to sugar via the Calvin cycle[11]. The reaction pattern is in accordance with the results already reported here and also with the following findings (20° C., *p*H ≈ 7).

(1) On excitation of Chl*a*-670 and Chl*a*-680 in *Chlorella*, the life-time τ of the changes in absorption at

The name that counts in High Pressure

Ermeto Engineers have developed the largest range of high pressure fittings in the world. The couplings are made in mild steel, stainless steel, brass, aluminium alloy and high duty bronze. High pressure valves and flexible hose assemblies are also manufactured. A large number of non-standard fittings are produced to meet customers' individual requirements. Our technical staff are always ready to provide further information. The Ermeto Catalogue is an essential reference when designing high pressure circuits. We shall be happy to forward a copy on request.

420 mμ and 515 mμ are the same ($\tau_{420} = \tau_{515} = 2 \times 10^{-2}$ sec.) because oxidized cytochrome and X react jointly.

(2) On excitation of mainly Chl*a*-680, τ_{420} is greatly prolonged (up to $\tau_{420} \approx 1$ sec.), as only small amounts of X are formed for the reduction of oxidized cytochrome.

(3) In the case of spinach chloroplasts extracted with water, oxidized dyes with a redox potential up to ~ 0 V. can be coupled to X (ref. 4). This is shown by the observation that τ_{515} is greatly shortened (down to $\tau_{515} \approx 10^{-3}$ sec.) as X is oxidized in addition by the dyes.

(4) Vice versa reduced dichlorophenol indophenol (red. In.) can be coupled to Cyt0. In this case τ_{420} is greatly shortened (down to $\tau_{420} \approx 10^{-3}$ sec.) as Cyt0 is reduced additionally by red. In.

(5) Preliminary experiments show that CMU (*p*-chlorophenyl-dimethylurea) uncouples cycle 4 from oxygen production. Heating to 50° C. destroys cycles 3 and 4. Heating to 60° C. destroys cycles 1 and 2. At the same temperature, type 1 chlorophyll reaction ceases[2]. Probably reaction type 1 sensitizes cycles 1 and 2.

The reaction pattern of Fig. 2, derived from experimental observations, is similar to a hypothetical one given by Hill[12].

This investigation was supported by the Deutsche Forschungsgemeinschaft.

Note added in proof. (1) In the meantime the redox potential of cycle 2 has also been estimated experimentally. This was done as in the case of cycle 3 by coupling different substances (red. In., ferrocyanide, etc.) to Cyt0. The result is a potential of $\sim +0{\cdot}4$ V. (2) Prof. H. Kuhn has directed our attention to a publication of Prof. H. Kautsky[13] in which a pattern corresponding with Fig. 2 was derived from changes of fluorescence. The principal differences between both will be discussed in a later publication.

Effect of Spacing and Nitrogen-level on Floral Initiation in Cocksfoot (*Dactylis glomerata* L.)

COCKSFOOT, like many perennial herbage grasses, is a long-day plant[1], and is reported to have an obligate winter requirement for cold and short days[2] or cold alone[3], before floral initiation can occur. It has not been possible to satisfy this requirement artificially by cold or short-day treatment given to germinating seed or young seedlings, (Calder, D. M., and Cooper, J. P., unpublished data) although such treatment has been effective in *Lolium* and the winter cereals[1]. Preliminary observations suggested that spacing of plants and nitrogen supply might have an overriding influence on flowering in cocksfoot and the following experiment was planned to investigate these effects.

Two contrasting varieties, *Bc* 4542, a natural population from Israel, and *S*.143, a late-flowering variety developed at Aberystwyth, were sown outdoors on April 29, 1960. At the third-leaf stage 160 plants of each variety were transplanted into 8-in. pots containing steam-sterilized soil, 80 at the rate of 10 plants per pot and 80 at one plant per pot. These spacing treatments were further divided into high and low nitrogen-levels, the high nitrogen group having Nitro-Chalk added at the rate of 1 gm. per pot every 2 wks., while the low nitrogen-level group had no nitrogen added. There were thus four spacing/nitrogen treatments per variety, each treatment containing ten plants, replicated four times.

Table 1. FREQUENCY OF REPRODUCTIVE PLANTS IN SPACING AND NITROGEN TREATMENTS

Variety	One plant/pot High N	 Low N	Ten plants/pot High N	 Low N
Bc 4542				
Reproductive	35 (5)*	25 (3)	9 (2)	0 (0)
Vegetative	5	15	31	40
S. 143				
Reproductive	15 (4)	6 (4)	0 (0)	1 (0)
Vegetative	25	34	40	39

Variety, spacing and nitrogen differences all significant at $P < 0{\cdot}001$.
* Figure in parentheses denotes number of plants with heads initiated but not emerged.

Table 1 shows the number of plants in each treatment which produced heads by September 26 (150 days after sowing), the number which initiated inflorescences without ear emergence, and the number remaining vegetative. No further initiation would be likely to occur after this date, because of a decreasing photoperiod. Both spacing and nitrogen-level had a marked influence on floral initiation, although the Israel population produced a higher proportion of flowering plants than *S*.143 in practically all treatments. In the denser spacing with low nitrogen, only one plant out of 80 produced heads, while in the wider spacing with high nitrogen 87·5 per cent of the Israel plants and 37·5 per cent of the *S*.143 initiated heads. Although the level of nitrogen applied has not compensated for the more severe competition at the denser spacing, the spacing/nitrogen interaction is not significant, suggesting that nitrogen supplied at greater rates might overcome the effects of plant density.

Little work has been done on the effects of plant spacing on floral development in herbage grasses and cereals, and reports on the effects of nitrogen-level are somewhat conflicting. In winter rye, for example, Gott *et al.*[4] have shown that nitrogen has little or no effect on any stage of the flowering reaction in fully vernalized plants, but in unvernalized material a low nitrogen-level may slightly retard progress to flowering. Von Denffer[5], on the other hand, reports that nitrogen deficiency accelerates flowering in barley and wheat. Leopold[6] states that, in general, nitrogen-level may have a profound influence on stages subsequent to floral initiation, but not on initiation itself. In the present case, both spacing and nitrogen-level have had a pronounced effect on floral initiation in cocksfoot. None of the plants received any cold exposure and the photoperiod was more than 13 hr. throughout the experiment, which indicates either that wide spacing and high nitrogen-level have largely replaced the inductive requirement, or that dense spacing with low nitrogen have inhibited the photoperiodic response.

These results should have important implications for the management of cocksfoot swards for continued leaf production on one hand, or for seed production on the other. They also provide a possible explanation for the findings of Evans[7] on the effects of plant density on seed-yield in a number of herbage grasses.

It is a pleasure to acknowledge the facilities and encouragement given by the director, Prof. P. T. Thomas.

Effects of Light Intensity on Reproduction in *S*.48 Timothy (*Phleum pratense* L.)

In recent years the role of light intensity as a major factor controlling growth of herbage in the sward has been emphasized. The production of inflorescences in herbage grasses also appears to be influenced by light intensity in conditions otherwise known to favour the onset of floral initiation. Several investigators[1–3] have remarked on the reduced flowering obtained in the glasshouse in winter, when photoperiod and temperature are artificially maintained at summer-levels. Experiments in the glasshouse have shown that inflorescence production in *S*.48 timothy occurs readily in the spring and early summer, whereas floral initiation is sporadic and delayed when plants are exposed to similar photoperiods and temperatures in the autumn and winter. In an attempt to separate the effect of light intensity, which presumably exerts an indirect effect on flowering by influencing photosynthesis, from that of factors such as photoperiod, which have a direct effect on flowering, an experiment was conducted in summer to test the effect of reducing the natural light intensity on the reproduction of *S*.48 timothy.

In 1958, seed of timothy was sown on damp vermiculite on March 20. A few days after germination the seedlings were transplanted to 3-in. pots of soil maintained under 8-hr. day-lengths in an unheated glasshouse. After the production of 7–8 leaves, the plants were moved outside to soil beds and planted 5 in. apart. Three of the beds were covered with layers of muslin arranged on metal frames to give varying light transmissions; the fourth bed of plants was left uncovered to provide a control. During the first half of the experiment, integrated light readings under the different treatments were obtained with Megatron photometers; the percentage transmissions in terms of natural light decreased in the following manner: (*A*) control 100 per cent, (*B*) 60 per cent, (*C*) 51 per cent and (*D*) 33 per cent. Thermograph recordings showed reduced temperature differentials under the muslin covers compared with the control, but the mean daily temperatures did not differ substantially.

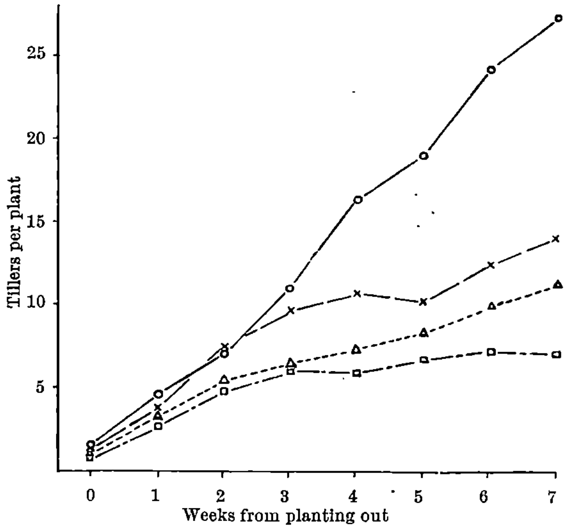

Fig. 1. Influence of light intensity on tillering in *S*.48 timothy. In full daylight, ○; in 60 per cent daylight, ×; in 51 per cent daylight, △; in 33 per cent daylight, □

The influence of light intensity on vegetative growth was assessed from tiller numbers before the ears began to emerge (Fig. 1). Light intensity had a marked effect on tiller numbers, and a significant response began to appear 2–3 weeks after the beginning of the treatments. After 7 weeks the control plants had produced nearly four times as many tillers as comparable plants in the densest shade; and this trend continued to the final harvest (Table 1). Several plants receiving only 33 per cent of the

natural light carried only three or four living tillers when the experiment was terminated. The mortality of new tillers was very high in this degree of shading.

Ears began to emerge on the main stems, first on the control and lightly shaded plants and later on the plants in dense shade. The final results for days to energence of the ear (Table 1) showed increasingly delayed emergence which became significant when the light was reduced from 51 to 33 per cent of full daylight. To some extent, this trend was reflected in the mean leaf numbers to ear-emergence, which also increased in the densest shade, but the leaf number in full daylight was exceptionally high. However, at the lowest level of light, the delayed ear-emergence, in those plants that did flower, was accompanied by a complete suppression of reproduction in about a third of the main stems (Table 1). These shoots showed internode elongation similar to that of flowering shoots, but micro-dissections at the final harvest revealed strictly vegetative apices. Length of ear in the flowering shoots also showed the effect of light intensity. In normal light conditions, ears averaged almost 10 cm., whereas, as the shading was intensified, the length decreased progressively to approximately 6 cm. Unpublished evidence from other experiments has revealed a good linear relation between ear-length and total floret number in this variety ; thus a direct relation between light intensity and potential seed yield per shoot is indicated. The mean number of ears per plant decreased to one-sixth as the light intensity fell from full daylight to dense shade, with the result that the percentage of fertile tillers per plant was also markedly influenced.

These results show that reduced light intensity appreciably affects both vegetative and reproductive growth in *S*.48 timothy. The total daily radiation received by plants in the densest shade increased from 80 to more than 100 cal. cm.$^{-2}$ throughout the period of the experiment, an intensity frequently exceeding that found in the glasshouse during autumn and winter. Similarly, the light intensity near ground-level in developing herbage stands falls in spring to less than 20 per cent of full daylight[4,5], which would suggest that a proportion of the shoots may not receive sufficient light for inflorescence initiation. This may in part account for the elongated, sterile tillers which are observed frequently in timothy seed crops.

Artificial Production of Buds fom the Embryos of *Cuscuta reflexa*

This communication forms part of an extensive programme on the *in vitro* culture of embryos and ovules. The observations are of interest in that the parent embryo produced additional 'adventive' embryos.

Embryos of *Cuscuta reflexa* (0·5–2·5 mm. long) were cultured on a modified White's medium containing minerals + sucrose (5 per cent) + casein hydrolysate (400 mgm./l.) + indole-3-acetic acid (1 mgm./l.).

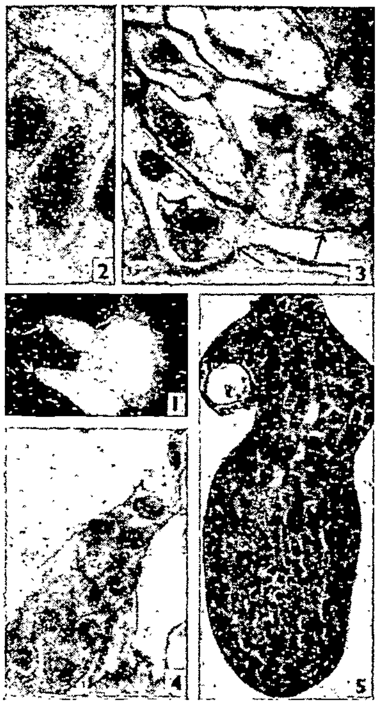

Fig. 1. Fifty-day-old culture of zygotic embryo showing adventive embryos at the radicular end (arrows); note the narrow apical end above. (× *c*. 5·3)

Figs. 2 and 3. Portions enlarged from a transection of the 'radicular' end of zygotic embryo, 40 days after inoculation, showing a dividing cell and two-celled proembryo (arrow-marked) respectively. (× *c*. 233)

Figs. 4 and 5. Further stages in the development of adventive embryos. (Fig. 4, × *c*. 170; Fig. 5, × *c*. 100)

When relatively small embryos (0·5–1·0 mm. long) were taken, they did not pass through the normal stages of development but swelled considerably and ultimately became transformed into a mass of callus. Small, whitish or yellowish-green bodies differentiated from this mass within six weeks of inoculation. They strongly resembled normal embryos. When larger embryos (1·0–2·5 mm. long) were cultured, they produced seedlings within a month. However, callus developed at certain points from the 'radicular' end, and, as in the cultures of smaller embryo, adventive embryos differentiated either from the callus or directly from the superficial cells (Fig. 1). Sometimes 10–15 such embryos were produced in a single culture.

Externally these embryos of adventive origin resembled normal embryos in possessing a narrow apical end and a broader 'radicular' end (Fig. 1). During their development, some of the epidermal cells of the original embryo became large and meristematic and underwent a transverse division (Fig. 2) to form 2-celled proembryos (Fig. 3). Further irregular divisions resulted in a globular structure looking like an embryo (Fig. 4). As in Nature[1], the embryos, instead of passing into a heart-shaped stage, showed vertical elongation (Fig. 5) and ultimately the distal end differentiated into the shoot apex.

The formation of vegetative buds has been previously reported from the callus of tobacco and carrot[2–4] and the embryos of some orchids[5]. Reinert has emphasized the close resemblance of the vegetative buds arising from the callus of carrot tissue with adventive embryos. In the present work it has been shown that in their development these adventive structures pass through many important stages fully resembling those in the normal development of the embryo.

Some of the adventive embryos proceeded to form a normal shoot, but the majority callused if left in the same medium. This callus is capable of continuous growth and produces a fresh crop of adventive embryos, thus providing an unlimited source of similar material.

Transformation in Plants of Sodium Dimethyldithiocarbamate into other Fungitoxic Compounds

IN investigations concerning plant chemotherapy it was demonstrated that the fungicide sodium dimethyldithiocarbamate (NaDDC), having been taken up by cucumber seedlings (*Cucumis sativus* L.), has some chemotherapeutic activity against *Cladosporium cucumerinum*[1]. In work on the uptake and translocation of NaDDC by these plants I have found that dimethyldithiocarbamate could not be recovered from the tissues. Instead the presence could be demonstrated of three unknown fungitoxic compounds which have the same mode of action as NaDDC, but differ in chemical properties. These observations show that, in the plant, NaDDC is subject to certain transformations which most probably are of a biochemical nature.

I have found that the addition of plant sap to NaDDC strongly reduces its fungitoxicity. For this reason small amounts of NaDDC in plant sap ($\leqslant 20$ p.p.m.) cannot be assessed by a direct determination of the fungitoxicity of the sap. If, however, a solution of NaDDC (10 p.p.m.) in cucumber sap is chromatographed, the presence of a fungicide can be detected with an R_F value of 0·87. To this end the solvent propanol/water (85 : 15) is allowed to run down the paper for 16 hr. at 22° C. The chromatogram is developed according to Weltzien[2], by spraying with a conidial suspension and subsequent incubation. Highly satisfactory chromatograms were obtained by adding an equal volume of ethanol (96 per cent) to the sap and placing 0·03 ml. or a higher quantity of the resulting supernatant on 1 cm. of the starting line of Whatman paper No. 3 ; the strips were developed by placing them on a metal frame stringed with nylon threads and subsequent spraying with a conidial suspension of *Glomerella cingulata* in a glucose-mineral salts medium (10^7 conidia/ml.). In this medium *G. cingulata* is highly sensitive to dialkyldithiocarbamates[3]. The strips were incubated for two days in a moist glass box at 27° C.

If a chromatogram is made of NaDDC dissolved in water (Fig. 1*a*) instead of in plant sap, a fungicide is detected at the same spot (R_F 0·87). Yet, in neither of these cases does the spot contain NaDDC. Instead the presence of its copper salt, $((\mathrm{CH_3})_2\mathrm{N}\underset{\overset{\|}{\mathrm{S}}}{\mathrm{C}}\mathrm{S})_2\mathrm{Cu}$, could be demonstrated spectrophotometrically by Dr. M. J. Janssen. Apparently, under the present conditions, NaDDC forms a chelate with copper from the paper.

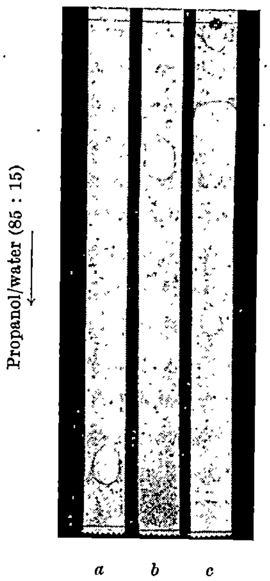

Fig. 1. Paper chromatograms of *a*, NaDDC dissolved in water (0·03 ml. of 33 p.p.m.); *b*, 1 : 1 alcoholic solution of sap from hypocotyls and cotyledons of cucumber seedlings after uptake of NaDDC by the roots (0·03 ml.); *c*, the same solution as in *b* (1·2 ml.)

Without previous chromatography the presence of small amounts of NaDDC in plant sap cannot be revealed on paper ; this suggests that the sap contains antagonists of NaDDC which are separated from the fungicide by the chromatographic procedure.

Once this method of detecting NaDDC in plant sap had been developed, I chromatographed the sap of cotyledons and hypocotyls of ten cucumber seedlings which had been standing for 2 days with their roots in 50 ml. of a 150 p.p.m. solution of NaDDC. Development of the strip, to our surprise, revealed a fungitoxic compound with an R_F value of 0·27 (Fig. 1*b*) while no fungicide could be detected with an R_F value of 0·87. If, moreover, the sap was concentrated about forty times, two other fungitoxic compounds (R_F values 0·03 and 0·58) were visible as well (Fig. 1*c*).

All three fungicidal compounds have the same mode of action as dimethyldithiocarbamate, since they could be counteracted by the addition of histidine or dibutyldithiocarbamate[4] to the nutrient medium used for spraying the strips. I therefore must assume that the three unknown compounds are derivatives of dimethyldithiocarbamic acid, which most probably have been produced by mediation of plant enzymes.

This transformation of NaDDC into other compounds which exert fungitoxic activity was also found to occur in broad bean plants (*Vicia faba* L.) and in chicory (*Cichorium intybus* L.).

It seems possible that biochemical transformation products of NaDDC in the plant are responsible for the observed chemotherapeutic effect.

I thank Dr. A. Kaars Sijpesteijn for many helpful suggestions. This work was carried out as part of the programme of the T.N.O. Research Unit for Internal Chemotherapy of Plants, at the Laboratory of Phytopathology, Wageningen, The Netherlands.

ENTOMOLOGY

Induced Changes in the Amounts of Material in the Neurosecretory System of the Desert Locust

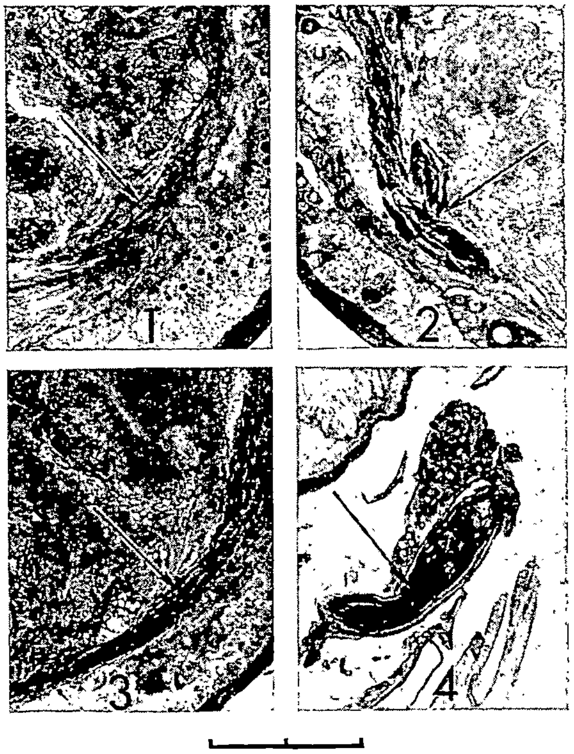
Mature adult female *Schistocerca gregaria* contain large amounts of neurosecretory material in the corpora cardiaca, the nervi corporis cardiaci I and the neurosecretory cells of the pars intercerebralis of the protocerebrum[1]. The neurosecretory systems of 2-week-old females, reared without males, similarly contain large amounts of stainable material; in these females, the terminal oocytes are largely undeveloped.

Forty-five minutes after administering high-frequency electrical shocks (10 V., 40 pulses/sec. for periods of 15 min. or longer) through the optic nerves of 2-week-old females, reared without males, the neurosecretory systems are almost devoid of stainable material (Fig. 1). Low-frequency electrical shocks (10 V., 40–75 pulses/min. for 15–30 min.) administered through the ventral nerve cord, the surface of the brain or through the optic nerves, result in the appearance of a very large excess of material along the nervi corporis cardiaci I (Fig. 2) and within the storage regions of the corpora cardiaca, compared with the operated controls (Fig. 3).

These effects of high- and low-frequency electrical stimulation are not necessarily inconsistent. It is probable that both kinds of stimulation accelerate movement of neurosecretory material along the nervi corporis cardiaci I and into the corpora cardiaca (and presumably into the blood). Low-frequency stimulation illustrates the early stages of the process; high-frequency stimulation the final stages.

Depletion of material in the neurosecretory systems of 2-week-old females, reared without males, also results when the insects are rotated in a flask for 45 min. in such a way that they are continually turned upside down and continually struggle to regain their normal orientation. Hodgson and Geldiay[2] record a diminution in amount of neurosecretory material in the corpora cardiaca of *Blaberus craniifer* following similar electrical stimulation and enforced activity.

Adult females killed during their first observed copulation reveal amounts of neurosecretory material along the nervi corporis cardiaci I (Fig. 4) and within the corpora cardiaca which are remarkably similar to the amounts along the nerves and in the glands of females after low-frequency electrical stimulation. Twelve hours after copulation, the material in the neurosecretory system is in small amount, resembling the condition following high-frequency electrical stimulation and enforced activity. It is clear that in this respect electrical stimulation and enforced activity mimic the effect of the natural stimulation of copulation.



Figs. 1–4. Photomicrographs of brain sections of *S. gregaria* after various treatments. Heads fixed in Bouin's fluid and sections stained with paraldehyde–fuchsin following permanganate oxidation. Arrows point to the nervi corporis cardiaci I in each figure; neurosecretory material appears black. 1, Nervi corporis cardiaci I in brain of female after 15 min. of high-frequency electrical shocks through the optic nerves; amount of neurosecretory material negligible. 2, Nervi corporis cardiaci I in brain of female after 15 min. of low-frequency electrical shocks through the optic nerves; very large amount of neurosecretory material present. 3, Nervi corporis cardiaci I in brain of female after electrodes had been in position in the optic nerves for 15 min., but the animal not stimulated (operated control); amount of neurosecretory material intermediate between 1 and 2. 4, Nervi corporis cardiaci I just beneath the brain; female killed *in copula*; very large amount of neurosecretory material present

Norris[3] has shown that copulation in *S. gregaria* is normally necessary for the development of eggs to their full size, preceding oviposition. Further, neurosecretory cells are necessary for egg development in this species[1]. The present observations suggest that copulation in *S. gregaria* makes available larger amounts of neurosecretory material for the full development of the eggs.

It should, therefore, be possible to simulate the effect of copulation on egg development by subjecting virgin females to electrical shocks or enforced activity. The results of electrical stimulation are inconclusive, since, although the terminal oocytes develop rapidly following the treatment, so also do the terminal oocytes of the operated controls. It is known that injury can accelerate maturation in the desert locust[3]. Enforced activity in 14-day-old females reared without males produces changes in the amount of material in the neurosecretory system similar to electrical stimulation, but the insects are not injured in the process. Fourteen 14-day-old females, reared without males, were subjected to enforced activity for 1 hr./day for 3 days. Dissected seven days later, the terminal oocytes measured 5·56 ± 0·64 mm.; 10 control females placed in the flask but not rotated possessed terminal oocytes 2·69 ± 0·57 mm. long seven days later. This result supports the hypothesis that the availability of neurosecretory material is important for egg development.

Hodgson and Geldiay[2] have suggested that the loss of adrenalin-like activity of extracts of corpora cardiaca of *Blaberus craniifer* following electrical stimulation or enforced activity should be correlated with the disappearance of neurosecretory material from the glands. It is difficult to reconcile this view with Cameron's observation[4] that the corpora cardiaca of *Periplaneta americana* yielded extracts with adrenalin-like activity, even after the nervi corporis cardiaci had been cut some time previously. The present results suggest that the release of neurosecretory material from the corpora cardiaca of *S. gregaria* has a positive effect on oocyte development; experiments in progress indicate that an adrenalin-like substance is produced from the *glandular* parts of the corpora cardiaca in *S. gregaria*.

I am grateful to the Anti-Locust Research Centre, London, for providing the locusts used in this work; and to Mr. W. Mosley for making the photomicrographs.

PSYCHIATRY

Spike and Wave Discharges and Alterations of Conscious Awareness

During a study of the mental concomitants of electroencephalographic changes in human beings suffering from petit mal, it was observed that changes in level of awareness did not coincide with the onset and cessation of surface spike and wave activity.

The minimal clinical signs of petit mal attacks are usually accompanied by the most obvious and dramatic electroencephalographic evidence of surface electrical changes, yet no other evidence of pathology in the nervous system has so far been discovered. The clinical accounts of the condition include all degrees of interruptions of conscious awareness with variations in form and frequency of the spike and wave activity. Our work was restricted to patients exhibiting typical clinical petit mal, with the classical bilaterally synchronous 3/sec. spike and wave activity seen on the electroencephalogram usually lasting 3–30 sec.

Eight patients were examined during the simultaneous recording of the electroencephalogram, certain peripheral autonomic changes and the interview. In all, 1,075 petit mal attacks were clinically observed. Five cases were recorded for a total of 31¼ hr. during which 91 attacks were recorded: in addition 3 cases were studied intensively for a total of 97½ hr. during which 684 attacks were recorded, and this latter group formed the main material for this work. Particular attention was paid to alterations in conscious awareness correlating with episodes of spike and wave activity of more than 3 sec. duration. The investigation of mental state was by question and answer, so that the highest level of brain function was involved since an appreciation of meaning was necessary for a sensible answer.

The onset of spike and wave activity varied greatly as to amplitude, lateral predominance and time of recruitment to full amplitude (Fig. 1).

During period *A*, when the spike and wave activity had reached full amplitude, the patient was capable of speaking and answering questions, and during or following period *D* could similarly recall events; the cessation of speech did not coincide consistently with any change in the electrical records.

Questions given in period *C* could produce the response 'Mmmm ?' during this period, or the answer to the question during or following period *D*. Any movement by the patient during this period could be recalled after the attack.

In period *D*, when spike and wave activity had ceased, there was a variable delay before reply, but on other occasions an immediate response was forthcoming. There was often an increase in pulse-rate about 1½ sec. after the end of spike and wave activity.

In period *B*, the patients were unable to respond to questions or to recall afterwards events during it. They were capable of a variety of movements and changes in facial expression (for example, smiling), and very frequently in two patients it was noticeable that, although they often turned their heads to one side, they could still return their gaze to look at the observer as spike and wave continued even when he changed his usual position from one side of the bed to the other before or after the attack had started.

It appeared from the above that the patients could speak for 3 sec. after the onset of an attack. They could perceive speech for 1½ sec. before the end of spike and wave activity, since they could answer the question or on occasion reply 'Mmmm ?' after the end of the attack. It also appeared that the ability to speak was sometimes delayed for some seconds after the spike and wave activity had ceased. It was observed that changes in expression of the eyes occurred before and after the end of spike and wave activity.

Alterations in pulse-rate, psychogalvanic skin response and respiration rarely correlated during the incidence of spike and wave activity. In one patient changes in pulse-rate were clearly seen; occasionally there was an increase in rate which usually occurred about 1½ sec. after the end of spike and wave; but it could also occur some seconds before or after the end of the attack. Changes before the onset of the attack were inconsistent and were complicated by sinus arrhythmia.

In other circumstances it has been demonstrated that electro-physiological changes may not be coincident with changes in conscious awareness[1,2]. Bates[3] also has demonstrated that patients can talk up to 3 sec. after the onset of electroencephalographic spike

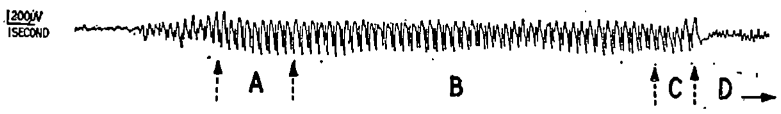

Fig. 1. Diagrammatic representation of attack.
Interval *A*, first 3 sec. of full-amplitude bilaterally synchronous spike and wave activity; *B*, duration of the attack excluding the last 1½ sec. of spike and wave that occur before any final slow wave; *C*, last 1½ sec. of spike and wave before any final slow wave; *D*, end of spike and wave and an arbitrary 10-sec. period

and wave activity; A. Jus (personal communication) using different methods has found that the cessation of spike and wave pattern does not coincide with the return to consciousness. Since the attempt in animal experiments is to simulate the clinical characteristics of human petit mal, it is important, as Jasper[4] has also urged, that a close examination be made of them. It may be worth while to study complex changes in psychological function in circumstances such as at operation when electrocorticograms and depth recordings are made.

These observations lead one to think of a common underlying process which variously affects consciousness and the cerebral electrical activity as recorded from the scalp. It has been shown that more refined techniques are necessary for the investigation and study of subtle alterations of conscious awareness. The causal connexion between spike and wave activity and alterations in consciousness deserves special investigation, since it appears that gross electroencephalographic changes are related to mental changes but that the points in time at which these events occur do not correlate.

Distribution of Piperidine in the Brain and its Possible Significance in Behaviour

Recent work on the use of piperidine for treating psychiatric disorders[1] has prompted an extensive programme here to investigate the mechanism of action of this simple chemical. The basis for using piperidine as a psychotherapeutic agent originally developed from the discovery that the agent antagonized the central actions of N-methyl 3-piperidylglycolate and other piperidinoglycolates possessing psychotomimetic properties[2]. These findings were particularly significant because piperidine has been found in human urine[3] and mammalian brains[4]. Piperidine might be an endogenous agent serving some normal function in the regulation of behaviour; that is, perhaps the amine is an endogenous psychotropic agent.

How much piperidine actually enters the brain after the agent is administered in an effective dose would be significant. Experiments were therefore conducted in rabbits, using tritium-labelled piperidine. The material was made by reducing pyridine with tritium, using palladium as a catalyst. After repeated recrystallization of the hydrochloride salt, the final material had a specific activity of 285 μc./mgm. Adult male albino rabbits were injected intravenously with 100 mgm./kgm. of piperidine hydrochloride per kgm. body-weight. This dose produced marked muscle relaxation and sedation in rabbits. After 30 min., the rabbits were bled by carotid cannulation, and the brain was perfused with saline until all trace of jugular blood was removed. The brain was carefully removed and dissected. After being weighed in the frozen state, the brain segments were suspended in 20 volumes of 5 per cent formalin for a period of 24 hr. at room temperature, a procedure extracting over 99 per cent of the piperidine (the formalin extract was filtered and dried in an oven at 90°). Further preparation of the dried residue for counting in a liquid scintillation counter is described in ref. 5.

The greatest concentration of piperidine occurred in the caudate nucleus while other regions in the diencephalon contained much less than half the concentration of the caudate (Table 1). Within the telencephalon, the greatest concentration appeared in the anterior neocortex, and although the lowest concentration occurred in the white matter, the concentration in the corpus callosum was relatively high. Next to the caudate, the quadrigemmina contained the greatest concentration of piperidine. Distribution of piperidine into the various segments of the diencephalon and mesencephalon was fairly uniform. With the exception of the telencephalon, the distribution of piperidine between grey and white matter was surprisingly similar.

At present, it is not possible to relate the distribution of piperidine to its action on the central nervous system, although a few general remarks can be made. Preliminary findings indicate that the electrophysiological effects of the piperidinoglycolates in regions such as the reticular formation and caudate nucleus can be reversed by piperidine, which is a weak nicotinic agent. It remains to be seen whether the muscle relaxation and weakness, ataxia, and the generalized decrease in motor responsiveness produced by piperidine in rabbits can be attributed to the distribution of the drug in such regions as the anterior neocortex and caudate nucleus.

In view of the fact that piperidine is normally present in mammalian brain, the question arises as to its possible significance in normal brain function. Honegger and Honegger[4] have reported the concentration of about 0·05 μgm. of piperidine per gm. of rabbit brain, which is approximately one-tenth the concentration present when 100 mgm./kgm. of the drug is administered (Table 1). When one considers that piperidine normally may be localized in certain brain regions, and that it appears to be excreted rapidly in quite large amounts (20 mgm./day in

Table 1

Vesicle	Derivative	Counts/mgm.
Telencephalon	anterior neocortex	6·6
	posterior neocortex	5·3
	pyriform cortex	3·5
	hippocampus	3·1
	white matter	1·8
	corpus callosum	3·2
Diencephalon	corpus striatum	2·5
	caudate nucleus	10·8
	lateral thalamus	1·7
	medial thalamus	3·1
	hypothalamus	4·8
Mesencephalon	tegmentum	3·3
	foot of mid-brain	3·2
Rhombencephalon	cerebellum	3·8
	pons	3·5
	medulla	3·6
	quadrigemmina	7·5

Localization of tritium-labelled piperidine in various regions of rabbit brain. Radioactivity is expressed in terms of counts/min./mgm. wet weight tissue. Since the ratio unlabelled piperidine/tritiated piperidine = 100, and since the specific activity of the tritiated material is 285 μc./mgm., 1 μgm. of piperidine is equal to approximately 3,000 c.p.m. The total amount of piperidine in a rabbit brain weighing 8 gm. would then be approximately 5 μgm. 30 min. after injection.

human beings)[3], it is quite conceivable that the endogenous piperidine may be influencing behaviour. Von Euler[3] had speculated that, because of its nicotinic property, piperidine may be regarded as an endogenous 'synaptotropic substance'. An important problem is to determine whether piperidine is synthesized within the body or arises from some exogenous source. In plants, piperidine and other cycloalkylamines are derived from amino-acids such as lysine, ornithine and proline[6]; but there is no evidence that such biosynthetic pathways can occur in mammalian systems. The presence of piperidine and other volatile amines in the central nervous system[4] nevertheless suggests the existence of many endogenous agents capable of influencing or regulating neural function. One exogenous source of piperidine is directly through the intestinal flora which can decarboxylate lysine to cadaverine, while the latter product is de-aminated and cyclized to form piperidine.

This work was supported by grants from the Mental Health Fund, State of Illinois, and the Teagle Foundation.

We are indebted to Abbott Laboratories for preparing the tritiated piperidine.

STATISTICS

Nodal Analysis of Associated Populations

A METHOD of subdividing an associated population the individuals of which are specified by the presence or absence of a number of attributes has been described previously[1]; the process is ultimately derived from the R-techniques of factor analysis, and the groups of individuals so obtained will be called R-groups. The attributes may similarly be subdivided into Q-groups by the corresponding Q-techniques. There results a 2-way table in which every attribute-individual record is referred to one of each kind of group. The requirement is to extract from this table the most concentrated groups of records, the attribute-individual noda around which the population may be regarded as varying. The problem is essentially that of establishing coincidences between R and Q factors; even in normal factor analysis the coincidences are impaired in the formation of the correlation matrix[2,3], and in a subdivision process involving successive correlation matrices the divergence may well be considerable.

Despite many attempts, we have found no way of operating directly on the 2-way table, and have therefore devised a method which involves finding the best possible coincidences with each direction taken as reference direction in turn, followed by collation of the two sets of results so obtained. The population is first R-divided, producing a group of individuals defined by the possession of the attribute a with the highest loading on the first centroid R-axis. The same population is then Q-divided; that individual (i') which, of those possessing a, has the highest loading on the first centroid Q-axis is used to delimit the group in the other direction. The residual group is similarly delimited by the individual with the highest loading among those not possessing a. Each resulting group we call an RQ-group. The division is continued to the significance-level required, resulting in a series of R-groups, with each of which is associated its corresponding RQ-group. It will normally be desirable to set a lowest acceptable limit for the loading of i'; if no individual attains this level, RQ is set $\equiv R$. The transpose of the entire process similarly gives a series of Q-groups together with their corresponding QR-groups.

Collation consists in taking one group from each side and subjecting the pair to a logical 'and' operation, whereby only those records common to both tables are retained. The conditions for collation are obtained from the singly defined (Q- and R-) tables. If any R-individual possesses all the Q-attributes and any Q-attribute occurs in all the R-individuals, QR is collated with RQ; the result is a nodum. If any R-individual possesses all the Q-attributes, but no Q-attribute occurs in all the R-individuals, QR is collated with R; the result is an R-subnodum. The transposed situation will give a Q-subnodum. If neither condition is fulfilled, all records common to Q and R are discarded. In the unlikely, but perhaps not impossible, case where collation is permissible but the nodum vanishes, the coincidence may be treated as intersecting subnoda.

The noda are extremely concentrated, and contain all the genuinely central information at the significance-level in use. They are not, however, necessarily all the same type. All are defined in the form $(a'i')$; but a nodum may also contain a and/or i (the attributes and individuals which define the non-residual R and Q groups), and the presence of these may be regarded as conferring a rise in status on the nodum. The subnoda constitute a penumbra of diffuse groups, some at least of which would become noda were the subdivision to be carried further on one side or the other by lowering the significance-level; they are always defined as (a') or (i'), but their status can rise to $(a'\ i)$ or $(i'\ a)$.

Our existing *Pegasus* subdivision-programme limits the analysis to a 76 × 76 population matrix. As yet, we have applied the method only to ecological data, but with very promising results. Whereas our earlier R-subdivisions[4,5] gave only groupings of quadrats on species-attributes, the 2-way tables provide a double abstraction in terms of both plant and habitat: the doubly defined noda thus represent true 'vegetation-units' in the widest sense.

FORTHCOMING EVENTS

Monday, July 10—Friday, July 14

INTERNATIONAL COMMITTEE OF DIETICIANS, and the BRITISH DIETETIC ASSOCIATION (at Church House, Westminster, London, S.W.1)—Third International Congress of Dietetics. Theme: "Tradition, Science and Practice in Dietetics".

Tuesday, July 11—Thursday, July 13

ASSOCIATION FOR THE STUDY OF ANIMAL BEHAVIOUR (in the Department of Zoology, University of Cambridge), at 10 a.m. daily—Symposium on "Orientation and Migration"; and Annual General Meeting.

Saturday, July 15—Sunday, July 16

BRITISH ACADEMY OF FORENSIC SCIENCES (at the Londoner Hotel, Welbeck Street, London, W.1)—Meeting on "Crime-Responsibility, Investigation and Treatment". (Second Annual Scientific Meeting.)

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

PRINCIPAL LECTURER (preferably with teaching and industrial experience) IN THE DEPARTMENT OF MATHEMATICS—The Registrar, Welsh College of Advanced Technology, Cathays Park, Cardiff (July 15).

LECTURER or ASSISTANT LECTURER IN MATHEMATICS at the University College of the West Indies—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (July 17).

POSTDOCTORAL FELLOW IN ORGANIC CHEMISTRY, to carry out research in the carotenoid field in collaboration with Prof. B. C. L. Weedon—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (July 17).

SCIENTIFIC OFFICER/SENIOR SCIENTIFIC OFFICER (with a first- or second-class honours degree in engineering or equivalent, and preferably an interest in stress analysis or the theory of elasticity), for research on wood machining processes and fundamental studies of the theory of cutting—Forest Products Research Laboratory, D.S.I.R., Princes Risborough, Aylesbury, Bucks, quoting Ref. FPRL 3W (July 17).

ASSISTANT BIOCHEMIST (with a degree or equivalent qualification in chemistry, and experience in, or wishing to take up clinical biochemistry)—The Secretary, Welsh National School of Medicine (University of Wales), 34 Newport Road, Cardiff (July 22).

ASSISTANT LIBRARIAN (Grade B) (with a good honours degree) in the University Library, to be Sub-Librarian for the Faculties of Medicine and Veterinary Science—The Registrar, The University, Liverpool, quoting Ref. CV/N (July 22).

RESEARCH ASSISTANT (graduate in botany or graduating this year) IN THE DEPARTMENT OF BOTANY, to assist the Professor in the establishment and maintenance of a collection of plant organ and tissue cultures and in research involving these cultures—The Registrar, University College, Singleton Park, Swansea (July 22).

RESEARCH FELLOWS and RESEARCH ASSISTANTS (with a good honours degree or equivalent in engineering, mathematics, physics or metallurgy) IN THE DEPARTMENT OF AERONAUTICS AND ASTRONAUTICS—The Secretary and Registrar, The University, Southampton (July 22).

ASSISTANT LECTURER IN THEORETICAL PHYSICS—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1 (July 24).

RESEARCH ASSISTANT (with a good degree in either physics with geology or geology with physics) IN THE SEDIMENTARY RESEARCH LABORATORY, to assist in establishing and operating an X-ray unit, and to undertake research on the application of X-ray techniques to the mineralogy of sediments—The Bursar, The University, Reading (July 24).

LECTURER IN MECHANICAL ENGINEERING—The Registrar, The University, Sheffield (July 29).

AGRICULTURAL CHEMIST, Scientific Officer or Senior Scientific Officer grade (with an honours degree and experience in research on soils and fertilizers), at Broom's Barn Experimental Station, Barrow, West Suffolk, to work on manuring of sugar beet—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (July 31).

LECTURER or ASSISTANT LECTURER IN ORGANIC CHEMISTRY—The Registrar, The University, Manchester 13 (July 31).

LECTURER (preferably with an interest in plant ecology) IN BOTANY at the University of Natal, Pietermaritzburg, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa and London, July 31).

LECTURERS or ASSISTANT LECTURERS (3) (with a recognized honours degree or equivalent qualification, and preferably with experience in teaching and/or research) IN THE DEPARTMENT OF MATHEMATICS, University of Malaya, Kuala Lumpur—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Malaya and London, July 31).

POSTGRADUATE SCHOLAR (suitably qualified in zoology or physiology) at the Gatty Marine Laboratory, St. Andrews, for work on the analysis of nervous systems of lower animals—Joint Clerk to the University Court, College Gate, St. Andrews (July 31).

SENIOR LECTURER or LECTURER (veterinary surgeon) IN VETERINARY MEDICINE, for duty at the field station near Potters Bar, Middlesex—The Secretary, Royal Veterinary College (University of London), Royal College Street, London, N.W.1 (July 31).

LECTURER/SENIOR LECTURER IN CLASSICAL ARCHÆOLOGY at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, August 11).

CHAIRS (2) OF MATHEMATICS at the University of Cape Town, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa and London, August 14).

CHAIR OF PHYSIOLOGY in the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, August 18).

READER IN ELECTRIC TRACTION at Imperial College—The Academic Registrar, University of London, Senate House, London, W.C.1 (August 21).

LECTURER (with an honours degree in zoology and preferably qualified to take courses in vertebrate embryology) IN ZOOLOGY at the University of Canterbury, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, August 30).

LECTURER IN PHILOSOPHY at the University of Canterbury, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, August 31).

WAITE CHAIR OF ENTOMOLOGY in the University of Adelaide, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, September 15).

LECTURER or ASSISTANT LECTURER IN PSYCHOLOGY at the University of Canterbury, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, September 30).

ASSISTANT (Grade B) IN THE DEPARTMENT OF MATHEMATICS—The Clerk to the Governors, Chelsea College of Science and Technology, Manresa Road, London, S.W.3.

ASSISTANT (man or woman) TO TEACH MATHEMATICS AND SCIENCE up to, and including, "O" level G.C.E.—The Headmaster, Cheney School, Cheney Lane, Headington, Oxford.

DEMONSTRATOR IN PHYSICS—The Registrar, The University, Nottingham.

LECTURER IN BIOCHEMISTRY IN THE DEPARTMENT OF APPLIED MICROBIOLOGY AND BIOLOGY—The Secretary, Royal College of Science and Technology, Glasgow.

LECTURER (well qualified and experienced in any branch of electrical engineering or related branches of physics, and preferably an interest in materials) IN ELECTRICAL ENGINEERING—The Assistant Registrar (Science), The University, Birmingham.

LECTURER (with doctor's degree) IN CHEMISTRY, to teach up to master's degree (lecturing in French)—Rector L. Gillon, University Lovanium, B.P. 121, Leopoldville XI, Republique du Congo.

LECTURER (with doctor's degree) IN MATHEMATICS, to teach up to master's degree (lecturing in French)—Rector L. Gillon, University Lovanium, B.P. 121, Leopoldville XI, Republique du Congo.

RESEARCH ASSISTANT (with, or expecting shortly to have, a first- or good second-class honours B.Sc. or equivalent, for example, A.R.I.C.) IN THE DEPARTMENT OF CHEMISTRY, for electro-chemical studies in molten salts—The Bursar, The University, Reading.

SENIOR RESEARCH ASSISTANT (preferably with research experience in the physics of discharges or allied fields of gaseous electronics), for work on the production and utilization of augmented ion concentrations in flame plasma—Dr. F. J. Weinberg, Chemical Engineering Department, Imperial College of Science and Technology, London, S.W.7.

TECHNICAL ASSISTANT (with practical experience in pot mending, metal cleaning, developing and enlarging of film and/or archæological draughtsmanship) IN THE DEPARTMENT OF ARCHÆOLOGY AND NICHOLSON MUSEUM—The Registrar, University of Sydney, Sydney, New South Wales, Australia.

APPOINTMENTS VACANT

CEMENT AND CONCRETE ASSOCIATION

invites applications from

PHYSICISTS

to carry out independent research and to take an interest in a broad range of applications of physics to the building industry.

The work of the Physics Group of the Materials Research Department includes fundamental studies of the properties of matter and strength of materials, measurement of heat flow, strain gauging, X-ray diffraction analysis, and design of instruments.

Scope exists for long-term work at the fundamental level as well as on applied physics projects, and the facilities include a Sirius computer.

The publication of results and attendance at scientific meetings is encouraged. The appointment will be made in the career range of £1,000 to £2,000, with possibilities of further advancement, and the post is permanent and pensionable.

Applications to Dr. A. R. Collins, Director of Research and Technical Services, Cement and Concrete Association, Wexham Springs, Stoke Poges, Buckinghamshire.

WORKS CHEMIST. A VACANCY OCCURS at the Extraction Plant of the Pyrethrum Board of Kenya at Nakuru for a Works Chemist. The duties will be chiefly analytical control but participation in factory operations is also included. The appointment is open to male candidates, who should possess a degree in chemistry or the equivalent Higher National Certificate in chemistry would be considered where the applicant has had approved experience. Salary: £1,400 by £50 to £1,750. The contract would be initially for a tour of three or four years, and subject to renewal. Return air fares paid up to three adult passages. Flat or house, with hard furnishings, available at a rental of not more than 15 per cent of salary with a maximum of £150 per annum. Provident Fund contribution of 5 per cent of salary, plus 10 per cent contribution by the Board. Medical and hospital benefits are offered, the Board paying two-thirds of the premium. Annual local leave of eighteen days is granted, with three or four months overseas leave at the end of the tour. Nakuru is in the Kenya Highlands amidst fine scenery, at an altitude of 6,000 ft., and has a pleasant, temperate climate. The Board's factory is for the solvent extraction of pyrethrum flowers, and is now being increased to treble its original capacity (1959) as a result of the rapid expansion of the Overseas market.—Applications, giving full details of age, education, qualifications and experience, etc., should be sent to the African Pyrethrum Technical Information Centre, 216 Grand Buildings, Trafalgar Square, London, W.C.2.

THE BRITISH OXYGEN COMPANY LIMITED

A Senior position is available in the Scientific Division for a

GRADUATE

IN CHEMISTRY OR PHYSICS

with experience in paint technology, particularly emulsion paints and preferably also in thermosetting resins.

The successful candidate will be required to carry out evaluation and technical service work on resins with special regard to paint applications.

Please apply to

THE ADMINISTRATION MANAGER,
SCIENTIFIC DIVISION,
THE BRITISH OXYGEN COMPANY, LTD.,
DEER PARK ROAD, LONDON, S.W.19.

AUSTRALIA

COMMONWEALTH SCIENTIFIC AND INDUSTRIAL RESEARCH ORGANIZATION

RESEARCH STAFF

(No. 464/233) (Several Positions)

The Organization's **Division of Textile Industry, Geelong, Victoria**, invites applications for research positions from honours graduates in science, or engineering with some years post-graduate research experience.

The Division, one of three constituting the Wool Research Laboratories, is broadly concerned with development of new physical and chemical techniques in wool textile processing and provides well-equipped laboratories for fundamental studies and full scale mill equipment for application of results. The wide field of research includes absorption studies on wool, fibre friction, permanent setting, shrinkage prevention, mechanical action of machines on wool fibres, servo-control mechanisms in processing and development of new machines.

The appointees will carry out duties in the following fields:

(i) Chemical studies on modification of wool fibres. This work would involve the study of reactions with a view to developing new fabric finishes;
(ii) The development of new physical methods for separating vegetable material from wool;
(iii) Physical studies on fibre friction, and the effects of lubricants:
(iv) Investigation of new methods of yarn production;
(v) Fibre behaviour in processing using radioactive and high speed photographic techniques.

Applications and enquiries from research workers in fields not strictly related to the above are also warmly invited.

SALARY: Dependent on qualifications and experience within the ranges, £A.1,510 to £A.2,265 per annum or £A.2,395 to £A.2,720 per annum.

EXPERIMENTAL OFFICER

(No. 464/232)

The Organization's **Division of Textile Industry, Geelong, Victoria**, also invites applications for a position as Experimental Officer from graduates in Electrical Engineering, or in Science with Physics and Electronics as major subjects (or equivalent professional qualifications). Experience in design of electronic equipment is essential.

The appointee will be required to assume full responsibility for an electronics laboratory. The function of the laboratory will be to develop special electronic devices for application in research on woollen and worsted processing; to advise research staff in projects of an electrical engineering nature: and to provide servicing facilities for all electronic equipment of the Division. First-class laboratory facilities available.

SALARY: Dependent on qualifications and experience within the ranges, £A.1,620 to £A.1,950 per annum or £A.2,070 to £A.2,330 per annum.

Salary for a woman will be £A.180 per annum less than corresponding rates for men.

Promotion within C.S.I.R.O. is by merit and may ultimately go beyond the upper limit of the range within which the original appointment is made.

Fares paid. Further particulars supplied on application to:

Mr. E. J. Drake, Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2,

to whom applications (quoting relevant Appointment number) should be addressed by August 5, 1961.

UNIVERSITY COLLEGE OF THE WEST INDIES

Applications are invited for (a) Lectureship or (b) Assistant Lectureship in Zoology (Entomology). Salary scales (a) £1,050 by £50 to £1,400 by £75 to £1,850 per annum, (b) £800 by £50 to £950 per annum, plus local allowance of £250 per annum (pensionable). Entry according to qualifications and experience, but in case of Assistant Lecturers and Lecturers below merit bar consideration is given to age in fixing salary. F.S.S.U. Child allowance. Settling-in allowance. Unfurnished accommodation at rental of 10 per cent of basic salary. Up to five full passages on appointment, normal termination, and triennial study leave.

Detailed applications (six copies), naming three referees, by August 7, 1961, to Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1, from whom further particulars may be obtained.

BIRKBECK COLLEGE

(UNIVERSITY OF LONDON)

Applications are invited for the post of Assistant Lecturer in Theoretical Physics (Professor of Theoretical Physics, Dr. D. J. Bohm). Salary scale, £800 by £50 to £950 plus £60 per annum London allowance.

Further particulars should be obtained from the Secretary, Birkbeck College, Malet Street, W.C.1. Closing date: July 24.

UGANDA

DEPARTMENT OF AGRICULTURE

CHEMIST

For research work on soil fertility problems connected with tropical crop rotations, manures and fertilizers. Candidates (male) must have an honours degree in agricultural chemistry or chemistry and should preferably have had at least one year's postgraduate training at an experimental station. Appointment on contract/gratuity terms for one tour of 21-27 months with emoluments in scale £1,221 to £2,448. Gratuity 25 per cent of total substantive emoluments. Free passages. Generous leave. Furnished accommodation usually available at low rental.

Apply, stating full name and giving brief particulars of qualifications and experience, to Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD/ 63/9/09/C1.

UNIVERSITY OF SHEFFIELD

Applications are invited for a post of Lecturer in Mechanical Engineering to begin duties on October 1, 1961, or as soon as possible thereafter. Initial salary according to qualifications and experience on the scale £1,050 by £50 to £1,400 by £75 to £1,850, with F.S.S.U. provision and family allowance. A grant towards removal expenses will be made.

Further particulars may be obtained from the Registrar to whom applications (four copies), should be sent by July 29, 1961.

FINANCING GOVERNMENT RESEARCH IN GREAT BRITAIN

IN the main, the report of the Council for Scientific and Industrial Research for 1960 is disappointing. The year has indeed been one of steady expansion, the pace and character of which have made it necessary, as Lord Hailsham points out in his introduction, to change the method of determining the Department's financial resources, a summary of which is given on p. 230 of this issue. The description of the change of methods is one of the most important features of the report; nevertheless, the report does not provide the information that might be expected, in view of the growing interest now being taken in the work of the Department, both in Parliament and elsewhere, on its contribution to the organization of Britain's research effort and the effective co-ordination of that effort. There is indeed a long and interesting section on the Department's relations with the universities and colleges of technology in Britain, dealing with the system of research grants and training awards; but a separate report is to be published surveying developments since 1956, emerging problems and trends in this field. Accordingly, that aspect of the Department's work is more appropriately considered when the promised report appears, just as the research associations and their work are now best discussed in the context of the separate report, *Research in Industry*.

Likewise, although no further information is given on the work of the Department's Intelligence Division, we are promised that the 1961 report of the Council will review at length the development of information services, and it is to be hoped that this report at least will supply the long overdue information on that part of the work of the Department. The Council, too, has been much concerned with the organization and maintenance of scientific representation, a function which the Department undertakes for all the Government departments concerned, and in which, in future, it may well be particularly concerned with the work of the new Department of Technical Co-operation. Here, the Council already recognizes from post-war experience that the true functions of scientific representatives grow naturally out of the local conditions in which they operate. The increasing importance of scientific questions in the political and commercial relations of the United Kingdom abroad has already made advice to ambassadors and other official representatives of the United Kingdom a major task of the scientific attachés. It is also increasingly important to promote good contacts between scientific organizations in Britain and corresponding bodies overseas, and the Government's own official scientific advisers continued to supply what is probably the most emphatic evidence of the consequences of the refusal to establish a Science Centre in London. Even now, there is little indication that official circles appreciate the extent to which the new National Lending and Reference Libraries of Science and Technology will, when fully operative, fall short of what such a Centre could have achieved in assisting scientific attachés in their task of securing an adequate supply of scientific and technical information from Britain.

The Council, however, recognizes that it is now necessary to consider extending the network of scientific representation so as to include not only countries that are scientifically and technologically advanced but also those that are at an earlier stage of development. Its decision that the time has come for a systematic assessment of the Government's needs in all areas which are not fully covered by the present network is welcome, as is the statement that the Council is also striving to ensure that the existing representatives have sufficient staff at their disposal to handle this increasing flow of important work. The Council has already embarked on a world-wide survey of the position in consultation with the Foreign Office, the Commonwealth Relations Office and the Board of Trade.

In view of what the Council itself writes in this connexion in the present report, one might have expected that the Colonial Office and the Department of Technical Co-operation would also be associated with this inquiry. Thus, the Department has been responsible since 1959 for the Tropical Products Institute, and this has led to a growing association of the Department of Scientific and Industrial Research with the needs of the dependent and emergent territories. The section of the report in which research into tropical problems is discussed refers to a steady demand from the less-developed countries for visiting experts, and they are continually looking for help in achieving a more effective utilization of their resources. The more advanced countries, on the other hand, request help with specific research problems or in finding new uses for over-produced commodities. Again, the report refers to investigations of fairly general interest, such as the possible physiological importance of tropical plants, and also the utilization of solar energy, which if it becomes economic could greatly benefit tropical and sub-tropical countries deficient in other sources of energy.

It is not, of course, the Tropical Products Institute alone which is concerned with studies of interest to the dependent territories, in the tropics and elsewhere. The Road Research Laboratory, the Building Research Station and the Forest Products Research Laboratory have long given assistance to such territories in particular fields. The Hydraulics Research Station undertakes, as part of its normal service to users, model studies and field investigations of problems arising overseas, and the territories concerned with the Station's present range of projects include Aden, Hong Kong, Iran, Mauritius, Nigeria and East and West Pakistan; while during the year a number of its staff visited both Ghana and Nigeria to advise on the need for, and possible scope of, specialist laboratories there.

These developments, however, raise more than the questions of liaison on which the present report focuses attention. They involve questions of co-ordination and allocation of resources in which the Overseas Research Council at least is concerned, and the Department of Technical Co-operation may well be in future. There is no indication in the report that this is appreciated; but the matter is one which the Minister for Science might well examine as a matter of urgency. Some of the most urgently needed research could well be in territories least able at present to finance such investigations, and there appears to be *prima facie* a danger that the Department's disposition to insist on payment by the beneficiary may result in important investigations not being initiated. A clear-cut recognition of responsibilities and allocation of resources as between the Overseas Research Council and the Council for Scientific and Industrial Research should go far to eliminate this risk.

For the rest, the report shows that the Council is manifestly seeking to ensure, by its allocation of resources, that the scientific effort of Great Britain is balanced in relation to national needs. It regards the assessment of the balance of research in the universities and colleges of technology as fundamental, because in each subject strong and effective research departments are needed to attract good staff and students and to supply the nation with well-trained research workers. It is anxious to secure balance in the Department's own research programme and many of the changes introduced in recent years are for that purpose. In future, international action is likely to contribute much to the achievement of balance, and the Council recognizes that it must be prepared to play its part in co-operative projects.

In particular, the Council re-emphasizes the importance of surveying research needs in particular subjects and industries, as has already been done, for example, by its Economic Committee in respect of the British machine tool industry, and the shipbuilding and marine engineering industries. The Committee appointed under Sir Arthur Pugsley's chairmanship to review the need for research on the fatigue of engineering structures made of metal has also reported, and the Council has accepted its report. The main recommendation is that a co-ordinated programme of research should be undertaken in specified fields relating to structural materials used under fatigue conditions, particularly materials in structural sizes and joint assemblies, whether welded, riveted, or friction-grip bolted. Other recommendations are concerned with the co-ordination of this research and the provision of design information, based on the results obtained, to practising structural engineers.

The Department is discussing the implementation of these recommendations with the Institution of Civil Engineers and other professional organizations, but meanwhile the Council has decided to make the report immediately available. The Council has also continued to examine various proposals and applications for support and development work in industry, and it hopes soon to complete a number of preliminary studies of such projects, particularly costly ones. These are all activities which clearly fall well within the scope of the Council, which, it should be remembered, unlike the Advisory Council on Scientific Policy, is an executive body, and as such is an important tool of that Council for carrying out its policy.

Nevertheless, while the steady attrition of the annual reports of the Department of Scientific and Industrial Research tends to rob them of interest, which shifts to those of the Advisory Council on Scientific Policy, there are passages in the present report which suggest the reflexion that the Council sometimes trespasses on the functions of the latter body, while failing to supply the information for a sound judgment as to the wisdom of the policy it advocates. Comment on the statement that the Council has found insufficient research effort in fields of science such as biophysics, geophysics, meteorology and oceanography, which lie between the main disciplines, could be premature in view of the promised report on the relations between the Department and the universities, and in any event the Council is obviously seeking to implement a recommendation of the Advisory Council on Scientific Policy. Indeed, it is the findings reported to the Advisory Council last year that are now guiding the Council's own policy.

The main interest of the present report, however, lies, as already stated, in the description of the new method of allocating the Department's resources. On its appointment, the Council believed that the inherited system of determining the man-power and finances available for the Department's work in agreement with the Treasury for five years at a time—subject to the annual approval of estimates by Parliament—would permit the Department's activities to be planned in advance with a reasonable assurance that, so long as could be foreseen, they would not suffer a financial cut. Rapid changes in the scientific and technological scene and the increasing cost of tools of research have, however, since made it almost impossible to forecast with any accuracy the nation's requirements as long as five years ahead; and two years ago, at the launching of the Department's second five-year plan, the Council expressed the view that it was possible to estimate the needs of research fairly accurately two years ahead but only provisionally five years in advance.

These doubts have been confirmed by events. In last year's report, the Council referred to the unexpectedly rapid growth of applications for research grants from universities and colleges of technology. This year it points out that the accelerated expansion of scientific departments in the universities must be matched by an increase in awards for postgraduate training, if it is to yield its full benefit. The Department is providing almost £300,000 for a space research programme, which only became possible after the five-year plan was prepared, and increasing use of the results of research in the conduct of Government business in itself leads to unforeseen demands on some of the Department's own research stations. Even more unpredictable are the requirements for very expensive pieces of scientific equipment, such as radio telescopes and particle accelerators.

Earlier this year, it thus became clear to the Council that adherence to the budget of the five-year plan would mean that much that should be done would be left undone, and that a more flexible financial instrument was needed. The new experimental scheme, which has been agreed with the Treasury, while providing reasonable assurance of future funds, is regarded as more adaptable to rapid and unpredictable change. Under it the Council will attempt to forecast its needs for five years in advance and will agree with the Treasury, subject to approval by Parliament: (1) the expenditure for the following year; (2) reasonably firm estimates for the two succeeding years (from which major departures will be made only if there are important changes in the scientific or financial situation); and (3) less-definite forecasts for the fourth and fifth years.

This system means that each year the Council will revise the estimates and bring them forward one year, so that they gradually become firmer. If the scheme works satisfactorily, the Council should be able to plan each year's expenditure alongside a fairly clear indication of likely expenditure in the years immediately following, and with some regard to longer-term plans. Whether this flexibility will be achieved at the cost of some decrease in security for research projects remains to be seen, but it would seem to be important, if confidence is not to be undermined, that the Department's annual budget should be large enough to provide a reasonable margin for adjustments.

The Council's understanding with the Treasury is that subject to the approval of Parliament the sums made available for the Department's work in what would have been the last three years of the second five-year plan will be more than 20 per cent above the original provision in the plan. Whether these provisions will give a sufficient margin of flexibility can scarcely be judged on the information disclosed in this report. What can be said is that, if the Council's annual report is to retain its importance and value, the legitimate segregation of detailed information to reports on particular phases of the Department's activities should not be carried to a point which hinders any general appraisal of the work of the Department as a whole. With Parliament taking a steadily increasing and healthy interest in the Department's work, it is the more essential that Parliament and public should be given ample information on which to judge the value of the work already being done, the needs and opportunities that are still not met and the way in which the Department's work impinges on that of other bodies contributing to the nation's research effort.

A. T. GREEN AND THE BRITISH CERAMIC RESEARCH ASSOCIATION

The A. T. Green Book

Dedicated to Arnold Trevor Green. By his colleagues of the British Ceramic Research Association. Pp. x+309. (Penkhull, Stoke-on-Trent: British Ceramic Research Association, 1959.) n.p.

Dr. A. T. GREEN, who had been director of research of the British Ceramic Research Association from its formation in 1948, retired from this post at the end of 1959. His colleagues in the Research Association have paid him a worthy tribute by publishing this collection of original papers. In doing so, they have not only recorded their feelings of affection and respect for Dr. Green but also have shown what a lively and successful example of a research association the British Ceramic Research Association is.

The first chapter describes the development of the British Pottery Research Association and the British Refractories Research Association, the two bodies which were amalgamated in 1947 to form the present British Ceramic Research Association. The second chapter deals with the growth of the research programme of the present Association and traces the continuity and development of the programmes from the two pre-amalgamation bodies. Green was appointed director of the British Refractories Research Association in 1937. He had, for seventeen years, been associated closely with the first director, Dr. J. T. Mellor, in the development from the small beginnings in 1917. It is interesting to note that in 1933 Green had sponsored work in the Refractories Department of the University of Sheffield on the use of magnesia as a refractory.

The British Potteries Research Association, although beginning its activities much later than the Refractories Research Association, started off in much more favourable financial circumstances, and in 1938 it purchased "Beechfield", a large house with extensive grounds at Penkhull in which stand the present laboratories of the Ceramic Research Association.

The success of Dr. Green's work is aptly summarized by A. E. Dodd at the end of his chapter on some features of the work of the Research Association, as follows: "At no stage in the forty years covered has it been possible to point to a specific experiment and say 'This revolutionized ceramics'. Yet this has been the period during which 'pot-banks' and 'brick-yards' have, for the most part, become modern factories. This same forty years is the period—the lifetime—of service given to the industry by Dr. A. T. Green".

But this quotation does not quite express the extraordinary facility with which Green had persuaded gradually an old-fashioned industry, divided into many small independent firms, to support and use the results of the laboratory investigations. Not only did Green do this, but also he always maintained the background and interest in fundamental scientific investigations, and in the period before his retirement he made special efforts to convince the industry that in the future they must look for far more long-term work from the Research Association than they had in the past. This present volume shows how this new programme has taken shape.

In all there are 27 separate papers in the volume, and it is impossible to comment in any detail on all of them; many of them are statements of the present position of work in hand. Of these the first technical paper on thermal shock in furnace structures is a good example. The experimental observations are clearly stated, and the lines along which understanding has to be sought are carefully set out; no attempt is made to present a final answer. The experimental results are quite fascinating; the pattern of the fracture in refractory bricks subjected to a temperature gradient is shown to be very largely associated with the size of the brick, the 3-in. brick cracking parallel to the hot face, the 6-in. brick cracking perpendicular to it and the 9-in. brick cracking in two places perpendicular to the heated face. It is shown that the most probable explanation lies in the distortion of the sides, and it is made quite clear that the semi-infinite slab approximation would not be appropriate in considering this problem.

The paper on the constitution of bone china contains a very interesting historical survey of the developments in the understanding of the nature of this material and the function of the raw material components; the problem does not appear to be solved completely.

The newer items that are coming into the programme are well exemplified by the article on special ceramics in which the work in progress in the Association using titanates and non-oxide ceramics such as boron nitride is described. This is a good example of A. T. Green looking ahead and taking steps to influence the direction of his research programme. Work on sintered oxides started in the laboratories in 1953, and in 1955 he accepted a Government contract for work on new dielectric materials. These programmes have been characterized by the fundamental way of viewing the problem.

The more homely aspects of the work in the Association are typified by the chapter on glass colours and the effect of the newer detergents on the durability of these colours. Other papers deal with strain in wall tile glazes, the firing of intermittent kilns, extrusion research, rheology and ceramic casting-slip control, chrome-magnesite refractories, to mention only a few. In all, there are twenty-six contributions in this well-deserved tribute to Dr. Green.

R. W. Douglas

THE WEST RIDING OF YORKSHIRE

The Place-Names of the West Riding of Yorkshire
By A. H. Smith. Part 1: Lower and Upper Strafforth and Staincross Wapentakes. Pp. xi+346. Part 2: Osgoldcross and Agbrigg Wapentakes. Pp. xi+321. Part 3: Morley Wapentake. Pp. xiii+278. (English Place-Name Society, Volumes 30, 31 and 32.) (Cambridge: At the University Press, 1961.) 35*s*. net each volume.

Since its foundation in 1924, the English Place-Name Society has produced 32 volumes dealing with 21 counties. The present three volumes form the first instalment of a total of eight concerned with the West Riding, and they cover almost all the county to the south of the Aire. The next three will cover the rest of the county; the seventh volume will be devoted to the interpretation—linguistic and historical—of the material thus assembled; and the eighth will consist of a general index to the place-names of Yorkshire as a whole. We must, therefore, wait for a discussion of the detailed evidence provided by this instalment; but, in the meantime, we can see what these volumes promise for the future and how they compare with the volumes that have already appeared for other counties.

Over the years, the Place-Name Survey has come to include an increasing number of minor names and field names, and this tendency is especially evident in these West Riding volumes. Many of the lesser names have no record earlier than the Tithe Awards of the mid-nineteenth century; but there is also a large number of names with forms from as early as the thirteenth century and even from the twelfth. All these names, together with the street-names of the larger settlements, are given a good deal of space in the present volumes. Complicated changes in the parish boundaries of the West Riding have involved many difficulties in the presentation of the material, but we are guided skilfully through the complexities of boundary changes. What is more, the area is highly industrialized, and, from beneath the modern built-up areas (with so many modern names), Prof. Smith has, in effect, disinterred an older landscape. The clearing of the wood, the draining of the marsh and the progress of rural settlement were activities that have left memorials in the place-names we use, often unthinkingly, to-day. Embedded in the detailed evidence there are many fascinating thumb-nail sketches of the history of individual names. The discussion of the name Halifax, for example, starts off with a review of early fanciful interpretations, and then proceeds with a piece of detective-like deduction. Another interesting sketch is that of the name Pontefract, which replaced the earlier Tateshale, now represented by the adjacent parish of Tanshelf.

This is the largest and most formidable county survey of place-names yet undertaken. The area is considerable; but, fortunately, the material is plentiful. These first three volumes whet our appetite for Volume 7 and for some general conclusions. The bulk of the names are Anglo-Saxon, but there is a strong Scandinavian element among them, and we look forward to a picture of the relative importance of English and Scandinavian names in different parts of the Riding. An idea of the bearing of this evidence on Yorkshire dialects will also be welcome; through the West Riding ran the boundary between Mercians and Northumbrians. We also look forward to knowing more about the West Riding Celtic names, not very numerous, but of especial interest because the Britons maintained the independent kingdom of Elmet here until well into the seventh century. Such parish-names as Monk Bretton, West Bretton and Walton suggest their own story. To the south, outside what may have been Elmet, there is Celtic evidence in the parish-names of Ecclesall and Ecclesfield near Sheffield, and in that of Wales not far to the east. In the north, just beyond the area dealt with in the present volumes, the name of Leeds is also Celtic in origin. Another category of names is that associated with Norman influence; the names are not many, but they give a feudal and French flavour to parts of the map of the West Riding, for example Hooton Pagnell and Laughton en le Morthen.

Two previous studies in the Survey (also by Prof. Smith) have dealt with the North Riding and the East Riding. The completion of the West Riding volumes will bring to an end a most ambitious undertaking: The completed survey of the place-names of the whole of Yorkshire will carry our knowledge of the evolution of the life and landscape of England a most important stage forward. At a different level of comprehension and enjoyment, it is pleasant to turn over the pages and see the rich and curious variety that characterizes English place-names. Parish names such as Cridling Stubbs, Purston Jaglin and Thorpe Salvin cannot fail to excite our curiosity. These three volumes are not only for scholarly reference but also for delightful browsing.

H. C. DARBY

SCIENTIFIC ATTITUDE TO MANAGEMENT

Management Sciences, Models and Techniques

Proceedings of the Sixth International Meeting of the Institute of Management Sciences, Paris, 7–11 September, 1959. Edited by Prof. C. West and Prof. Michel Verhulst. Vol. 1: Pp. xxix+602. Vol. 2: Pp. xiv+511. (London and New York: Pergamon Press, 1960.) 200*s*. net per set.

ESTABLISHED six years ago, the Institute of Management Sciences has made much more progress than even its enthusiastic founder members had cause to hope for. This is reflected in the *Proceedings of the Sixth International Meeting*, which was held in Paris during September 7–11, 1959, and which run to a weighty two volumes of concentrated report.

The meeting was supported by about a thousand participants from all parts of the world. Not unexpectedly, many of those attending came from the United States, and, again not unexpectedly in view of Britain's relative backwardness in management education, there were comparatively few British representatives. At present it would appear that other European countries and countries in the Commonwealth are showing greater interest in the scientific approach to problems of management than is the case in Britain.

Six years ago the complexity of management problems made it doubtful whether the scientist could make a noticeable contribution over a short period of time. During those six years the number of scientific personnel entering the management field has increased significantly, and there has been a corresponding if, as yet, limited advance along a number of sectors. Techniques like simulation, linear programming and the theory of decision-making have been applied to management tasks, sometimes with success verging on the phenomenal. Attention has also been paid to problem areas in production and inventory control, as well as to the place and performance of research and development departments.

These and related topics were all considered at the Paris meeting. Prof. Myron Gordon, of the Massachusetts Institute of Technology, showed that even the optimum amount of profit which a business should distribute can be analytically determined. Contributions from Norway and the Argentine gave examples of how little-developed industrial countries are using tools like operations research to stimulate their economies. From Britain, Prof. R. W. Revans presented a case-study to show how our hospital services need scientific help in their management, while F. de P. Hanika, now of Churchill College, Cambridge, presented a thoughtful paper describing the role of management sciences in training and education for management; his shrewd admixture of theory and practice should appeal to managing directors and teachers of management subjects in university or technical college.

Of the papers presented, however, a large proportion was directed to the area of business games. During the past few years there has been rapid progress in the development of analytical descriptions of entire business enterprises. These games are proving increasingly useful in management training as well as for research in investigating group interactions in industry and commerce; participants were able to sample games which had been developed and played in the United States, France, Denmark and Great Britain, and *Management Sciences, Models and Techniques* contains detailed descriptions of the game as well as comments from the players.

The two volumes make a noteworthy contribution to the application of science in management thinking and, by inference, indicate how ill-equipped many practising managers are to meet the challenge of the next decade. The need for a good basic education with more than a modicum of mathematics shines like a beacon on every page of this not inconsiderable book. So does the need for management scientists to eschew that extrapolative jargon which is already threatening to choke clear thinking and make them intelligible only to one another.

For such an important work the book is unevenly produced. Although intended for English-speaking readers, many outstanding American contributions are presented only as the briefest of abstracts; quite a number of contributions in French are set out in expansive detail, including the extraneous. It would appear that, for speed and economy, conference papers issued to participants have been printed by a number of different firms; when brought together to form a substantial book the effect is patchy and does not make for easy reading. Full contributions in one language with abstracts in the other might lead to the desired economies and produce more satisfying proceedings.

T. H. HAWKINS

TROPICAL FLORAS IN THE TERTIARY IN SOUTHERN ENGLAND

The Lower Tertiary Floras of Southern England. I.

Palaeocene Floras; London Clay Flora (Supplement). By Marjorie Elizabeth Jane Chandler. Pp. xi+354+Atlas of 34 plates. (London: British Museum (Natural History), 1961.) 200*s*. net.

A LARGE part of this book is a supplement to *The London Clay Flora* by Mrs. Clement Reid and Miss Chandler, published by the British Museum (Natural History) in 1933. In this joint work they gave a description fully illustrated with photographic reproductions of the fossil plants, mostly fruits and seeds, found in the London Clay, which is part of the Early Eocene of the south of England. They devised special methods of investigating the internal structure of these fossils, which are partially lignitized and partially pyritized and uncompressed. A great deal of information about their histology could be obtained and enabled close comparisons to be made with the corresponding organs of existing natural orders of flowering plants. It was possible to assign most of them to natural orders and, in a few instances, to existing genera. 234 species were described in the original work of 1933 : most were assigned to new genera and species. Miss Chandler now adds a dozen new genera and more than a hundred new species to the list. There are, in all, more than 50 natural orders represented in the London Clay. The geographical distribution of these orders to-day suggested that the London Clay flora was that of a tropical rain forest with a similar floristic composition to that of the present Indo-Malayan region. The Tethys Sea at that time included the present Mediterranean and extended from the Indian Ocean to western Europe, and this flora spread along the adjacent land areas. Miss Chandler's later work fully supports these views.

But, in addition to supplementing our knowledge of the London Clay flora, Miss Chandler makes important additions to our knowledge of the other Palæocene floras of England.

The Second World War interrupted much of her work, but in the previous eight years and in the period after 1944 much collecting has been done and there are many interesting and useful data about new localities. In the present work under review we find a systematic treatment of the Early Tertiary floras of southern England from Thanet, Woolwich and Reading Beds of the Pre-Ypresian to the Ypresian with the Oldhaven, Blackheath Beds and the London Clay. The geological relationship of these beds and the separate basins of the London and Hampshire areas is clearly explained. Their floras all suggest tropical conditions. There is no evidence for supposing that a cool climate existed during the Palæocene.

The systematic descriptions of the floras and their species occupy about three-quarters of the volume and are treated in a similar manner to *The London Clay Flora* by Reid and Chandler. The volume of illustrations contains 34 plates, which include more than 1,030 excellent reproductions of photographs of fruits and seeds.

Miss Chandler is to be congratulated on a great achievement. The work is marked throughout by accuracy, and the descriptions are always clear and unambiguous.

John Walton

K. TERZAGHI: FOUNDER OF THE SCIENCE OF SOIL MECHANICS

From Theory to Practice in Mechanics Soil

Selections from the writings of Karl Terzaghi. With bibliography and contributions on his life and achievement prepared by L. Bjerrum, A. Casagrande, R. B. Peck and A. W. Skempton. Pp. viii + 425. (New York and London: John Wiley and Sons, Inc., 1960.) 96*s*.

PROF. KARL TERZAGHI is one of the most interesting figures in the world of engineering science, and many believe him to be the greatest civil engineer of our day. Due to his pioneering research in Istanbul, leading to the publication of *Erdbaumechanik* in 1925, the study of the mechanical properties of soil was given a rational basis, and the science of soil mechanics, which is now studied by civil engineering students throughout the world, took its place among the other engineering disciplines.

Soil mechanics is itself divided into a number of specialities, for example the stability of earth dams, the design of pavements, the heaving of soil due to frost, etc., and it is astonishing how many of these various topics were first tackled systematically by Terzaghi, leaving it to others to develop along the lines he first indicated. This might have been deduced from his *Soil Mechanics in Engineering Practice* (1948) ; but it is brought out very clearly in this collection of his early papers, which trace in a fascinating way the development of soil mechanics, as we now know it, with the man. To the younger generation Terzaghi is already becoming a mythical figure. His James Forrest Lecture at the Institution of Civil Engineers in 1939 stirred their elders into a realization that soil mechanics was of vital concern to them ; now, in this work, all may come closer into contact with him and learn from his directness and integrity.

A few of the collected papers published here would have been available to readers in a big city with a good library. But the *Proceedings of the First Soil Mechanics Conference* (1936) are somewhat rare, and many will welcome the opportunity of having Terzaghi's contributions to it on their own shelves. Most of the other papers will be quite new, however, and of these the professional reports are the most valuable. Apart from their interest they provide a model of good prose.

The book has two particularly valuable sections. One, contributed by Prof. Skempton, assesses the importance of the concept of effective stress, discovered by Terzaghi, from which so much of the theory of soil mechanics is derived. The other, by Prof. Casagrande, is a biography of Terzaghi, which fills in some of the detail of the image which surrounds him. As he approaches his eightieth year, we are grateful to those who made this collection and edited the work. Few men of this stature emerge in each generation.

Kevin Nash

MELBOURNE SYMPOSIUM ON ANTARCTIC METEOROLOGY

Antarctic Meteorology

Proceedings of the Symposium held in Melbourne, February 1959. (Commonwealth of Australia: Bureau of Meteorology.) Pp. xviii + 483. (London and New York: Pergamon Press, 1960. Published for and on behalf of the Director of Meteorology, Melbourne, Australia.) 105*s*. net.

NO criticism of the contributors to scientific symposia such as the one here presented would be implied by the comment that, in some cases, it may be doubted whether the papers are of such lasting value as to justify a hard-covered book selling at a high price. There are, after all, the appropriate scientific journals as media for publication. This particular symposium was, however, a special case, held under the official auspices of the Special Committee for the International Geophysical Year and the Special Committee for Antarctic Research shortly after the conclusion of the International Geophysical Year.

The symposium (*Nature*, 183, 1503 ; 1959) was in fact a meeting of workers from the International Geophysical Year expeditions, then on their way home. In view of the fact that it was held so soon after the observations had been made, and with so little time for digestion, the content appears remarkably good. As might be expected from the numbers involved in this major scientific onslaught on Antarctica, the problems tackled are extraordinarily diversified—one dare not say comprehensive: there is, for example, little about oceanography or the sub-antarctic sea ice, though there is some interesting material for considering the role of the stratosphere; and, of course, local effects could only be sampled.

The forty papers printed were distributed between sessions on (1) local effects, (2) synoptic analysis and forecasting, (3) synoptic influences on lower latitudes, (4) general atmospheric circulation, (5) snow and ice characteristics, (6) heat and mass exchanges, and (7) climatology. In some of these fields, including both synoptic meteorology and the antarctic stratosphere, the book provides by far the richest reference material so far in print; the synoptic examples are, of course, largely drawn from a period far too short to be fully representative, and some of the contributors (if given longer experience in antarctic meteorology) might with advantage have drawn more on comparisons with earlier published synoptic situations. The work of Meinardus, Simpson, Palmer and Ramage—to quote a few—seems under-represented in the references used.

Until recent years only one or two general reference books existed from which the meteorologist working in antarctic regions, or his colleague concerned with antarctic effects on the weather and climate of the southern hemisphere homelands, could obtain guidance. The present work will be a very valuable addition to the libraries which such workers can consult—though for this purpose a book should have an index. It seems likely to take its place, for several years to come, among the four or five most used works on antarctic meteorology.

H. H. Lamb

MATHEMATICS AND LANGUAGE

Type-Token Mathematics

A Textbook of Mathematical Linguistics. By Dr. Gustav Herdan. (Janua Linguarum, Series Maior, Vol. 4.) Pp. ii+448. (The Hague: Mouton and Co., 1960.) 54 guilders.

THE application of statistical methods to linguistic problems goes back at least as far as Malone's suggestion (in 1778) that the order of writing of Shakespeare's plays might be ascertained by such tests. In the past fifteen years it has gained additional interest from the developments of 'information theory' and projects for mechanical translation. Various methods have been evolved, and some quite novel statistical techniques discovered: but a laborious search of both statistical and linguistic publications is needed to discover what has been done. A book which attempts a survey of the whole of this field therefore deserves some welcome.

Type-Token Mathematics has much the same scope as Dr. Herdan's earlier book *Language as Choice and Chance* (1956). It is considerably more than a rewritten and enlarged version, as it contains both new ideas and new material; several chapters are reprints of recent papers by the author. Its material falls into two parts (closely commingled): mathematical and philosophical. The mathematical parts are vitiated, unfortunately, by the extreme shakiness of Dr. Herdan's statistical technique: the innocent linguist must be urgently warned not to adopt any procedure that he recommends without advice from a statistician. Two examples will suffice to put the statistician on his guard: it is not true that if we use a significance test at the 1 per cent level "we shall be wrong once in 100 times with our assumption of a real difference" (page 105); and it is not true that "deviations [from the mean] exceeding three times the standard deviation" are very unlikely to occur by chance (page 287) when we are considering a variate which has (approximately) a Poisson distribution with an expectation of less than one (as on page 290). In the latter passage, it is regrettable that Dr. Herdan gives unreliable formulæ for α (the expected frequency in a second sample of a word occurring a small number of times in the first) and its variance, as the techniques for making reasonably accurate estimates form one of the most interesting developments of statistics applied to language. Dr. Herdan nowhere mentions these techniques, although his bibliography includes the paper containing them (Good, 1953).

The philosophical portions of the book are occasionally stimulating, but more often irritatingly vague and confused. A fairly extensive bibliography is given; unfortunately it fails to include several of the references in the text, leaving the reader to search for, for example, "Oettinger, 1957", with no further clue. In view of the sub-title it should be added that the book is essentially an exposition of Dr. Herdan's own, generally controversial, views—a perfectly proper purpose for a book in general, but most inappropriate for a 'text-book'.

A reader whose knowledge of both statistics and information theory is sufficiently sound to save him from being misled or confused may find some interesting material and some interesting ideas in the book, but is unlikely to find it good value for money. The beginner in these fields must be, reluctantly, warned to keep off it.

G. H. Toulmin

MATHEMATICS AND QUEUEING

Mathematical Methods in the Theory of Queueing

By A. Y. Khintchine. Translated by D. M. Andrews and M. H. Quenouille. (Griffin's Statistical Monographs and Courses, No. 7.) Pp. 120. (London: Charles Griffin and Co., Ltd., 1960.) 32*s*.

THIS beautiful little book breathes reason and modesty from cover to cover. It is written somewhat in the style of the classical French texts of fifty and more years ago—a style which allowed sufficient space for an honest exposition, and was not cramped by the present-day fashion for condensation and the pressure of costs. The publisher and the translators are to be congratulated for introducing the work to the English-speaking world, and the book will be of undoubted value to every mathematician interested in the theory of queues. A particularly pleasing feature is the way in which the results are developed; the mathematics is 'done', not merely indicated, and nowhere does the author state a result and refer the reader elsewhere for the details. Thus there is a satisfying aspect of completion about the exposition.

Part 1 is devoted to the theory which depends only on the arrivals and not on the nature of the service-time distribution. A 'simple' stream is defined to be one which displays stationariness, absence of after-effects, and orderliness; that is, the probability of k arrivals in any interval of time depends only on the length of the interval, and not on any arrivals before the start of the interval, and there cannot be two or more arrivals at the same instant. The theory of the simple stream is developed, and then extended by relaxing one or more of the conditions just stated. In particular, some properties of the stream without orderliness are obtained, and streams with limited after-effects are investigated.

In Parts 2 and 3 problems of service are considered. In a queueing system with several lines of service (in parallel) a customer on arrival may find that there is no service immediately available. He may wait until service is available, or may leave the line without waiting. In the former case one speaks of a "system allowing delay", in the latter case of a "system with loss". It is perhaps worth pointing out that Chapter 11 (the last) presents the general theory of a single-line system with an arbitrary service-time distribution. The distribution function for the waiting time is found in principle by a fairly simple method. The contents of the chapter are taken from a paper by the author, published in 1932, and present material which will be new to many readers.

The theory of queues has undergone considerable development in recent years. Some mathematicians think the development has gone too far. Whether this is so or not the book under review will serve to show that the phenomenon of queueing represents another human experience which has bowed to the forces of applied mathematics; the concepts that have been built around this experience have proved to be of the right kind, and sufficient in number, for the mathematical development to go 'with a bang'. Anyone who is in doubt as to whether applied mathematics is a living subject will find it rewarding and reassuring to read this book.

L. S. GODDARD

ARCHÆOLOGY OF OLD SMYRNA

The Annual of the British School at Athens
Nos. 53–54, 1958–1959. Pp. xii+312+74 plates. (London: The British School at Athens, 1960.) 105*s*. net.

WITH this number begins the serious publication of Old Smyrna, dug some ten years ago. Most of the articles on other subjects, to take these first, are also rather austere. Sinclair Hood and Piet de Jong describe a Minoan kitchen, Sinclair Hood, G. Huxley and N. Sandars a cemetery of the Late Minoan III Period, both near Knossos. Analysis of amber beads leaves their provenance uncertain. J. Leatham and Sinclair Hood describe some submarine work on sunken fish-ponds and harbours; work which, like the Mycenæan boat off Lycia, confirms that at present diving offers the bleakest prospects in archæology. R. Hope Simpson finds the rag of a Mycenæan settlement near Menidi, in Attica. J. M. C. Toynbee describes four interesting Roman portraits, dating from the Claudian to the Decian Period, in the Piræus Museum; and John Boardman describes a farmhouse inhabited about 450–350 B.C. at Pindakas in Chios, a site remarkable chiefly for a coin-hoard of about 350 B.C. Boardman has interesting things to say about the first-named 'magistrates' issues of Chios, and about her earliest bronze coins, which he would date about 375 B.C.

J. M. Cook introduces Old Smyrna in a topographical and historical résumé—a model of masterly brevity badly needed in this volume. The settlement at the north-east end of the Gulf goes back to Protogeometric times. "Aeolic" at first, it had become Ionic by about 800 B.C., which might agree with the story of its seizure by Colophon. The eighth century was the era of rounded houses. An earthquake about 700 B.C. destroyed the walls, which were not immediately replaced, while the new houses were rectangular. About 600 B.C., when a new wall had scarcely been finished, a new temple only begun, the Lydian Alyattes raised a siege-mound (still surviving, to the north-west) and took the city. After that, though quite densely inhabited by the fourth century, Old Smyrna never recovered its status, and was deserted for the present site before 300 B.C. J. K. Anderson, who describes the Corinthian pottery found, shows that Alyattes sacked the town well before the Early Corinthian style had run its course. Prof. Cook finds space for a mass of topographical information, subsidiary but never irrelevant.

John Boardman describes the Attic vases, some from good workshops. But the core of this instalment is an extremely painstaking hundred pages, by R. V. Nicholls, on the City Walls. The illustrations, through all their intricacies, maintain a high level of scientific exactitude and consistency; although even Mr. Nicholls grows weary in time of using all the symbols and *sigla* recommended by Sir Mortimer Wheeler, and finds (for example, in Figs. 7 and 10) that he can simplify with advantage. Somewhere in the text are many excellent points; for example, that the mound to the south-east of Gordium could also be a siege-mound, that the staked ditch of Iliad XII is more likely to be Iron Age than Bronze Age, that the step on the inner face of our Walls 2 and 3 might have supported a wall-plate to drain the walls' *chemi-de-ronde*, and that mud-bricks in the mid-seventh century changed to a size and shape more suitable for the new two-storey houses. It is, alas, typical that this last sensible conclusion should be mixed up with pages of metrological discussion (Nicholls believes, prematurely I feel, that only two constant lengths of foot existed and are known for the Classical Period.) These reach no firmer conclusions than one might expect, and lead by the way (p. 105) to such things as single bricks with dimensions on conflicting scales. Even Le Corbusier has not got to that. On important matters, like the arrival in the Greek World of the true arch, the citation of authorities seems most one-sided. For all its acuteness, the article is almost impossible to read. Page after page, one has to endure sentences like this: "The brick dimensions quoted on p. 101 are also of great interest in this regard, notwithstanding that it is not always possible to evaluate the different degrees of reliability with which they have been taken". Mr. Nicholls evidently knows his Herodotus and Homer. Yet, as stylists, they must mean nothing to him. Similarly, modern Athens has the most wonderful museums in the world, and the ugliest streets. Humanity, in its own home, has been sterilized.

HUGH PLOMMER

Genetica

By Prof. Enrique Sanchez-Monge y Parellada. Pp. xii+437. (Madrid: Enrique Sanchez-Monge y Parellada, Instituto Nacional de Investigaciones Agronomicas, 1961.) 380 pesetas.

THE present work by Prof. Sanchez-Monge is based on a previous book by him and Dr. Ramon Esteruelas published in 1952. The rapid development of genetics during the past few years has made rewriting necessary, though the objectives which animated the first work are unchanged. These were, states the preface, briefly to put into the Spanish language all the fundamental bases of modern genetics so that the reader may appreciate the importance of this discipline in pure and applied biology, medicine, psychology, agronomy, forestry, taxonomy, the improvement of plants and animals, microbiology and virology.

Such a book was highly necessary in Spain, where, it is alleged, outmoded ideas which should have been abandoned years ago still have a firm hold on the curriculum.

The present work differs in its general plan from the first one, principally in the change of title, and in the omission of two chapters on the improvement of plants and animals. It begins with an introductory chapter on reproduction, and then goes on to chapters on Mendelian heredity, qualitative and quantitative, the latter being preceded by a brief introduction to statistical analysis. It continues with an account of sex determination and sex-linked inheritance, types of evolutionary change, the role of cytoplasm in heredity, the genetics of populations and the physiology and nature of the gene. Then follows a chapter on genetical aspects of evolution, with special reference to mechanisms of speciation and to the species concept. Finally there are two chapters dealing with the genetics of micro-organisms and of man. Considering the wide field that the author has surveyed it is not surprising that treatment sometimes fails to achieve correct emphasis. For example, the chapter on human genetics contains no mention of the work of Penrose or Haldane, nor of the contributions of Harris in the domain of human biochemical genetics.

Five appendices contain: a short history of genetical discoveries, the international rules regarding symbols, a glossary of technical terms, a collection of problems and a list of recommended books. The book contains an admirably clear, concise and on the whole accurate account, in 437 pages, of present-day genetics, and is recommended to all students who read Spanish. It is well produced and illustrated and relatively cheap, though of somewhat inconvenient size. Each chapter contains a useful bibliography and there is a good index.

S. C. HARLAND

Proceedings of the Third World Orchid Conference

London, May 30–June 2, 1960. (Sponsored jointly by the American Orchid Society, The British Orchid Growers' Association and the Royal Horticultural Society.) Pp. 442+10 plates. (London: The Royal Horticultural Society, 1960.) 42*s*.; 6 dollars.

THE third World Orchid Conference, held in London at the beginning of June 1960, brought together more than five hundred persons, from thirty different countries, whose common interest was the study of the family Orchidaceae, albeit from many different points of view. Professional growers, amateurs and scientists were among those attending, and the numerous papers delivered, though with a distinct bias towards cultivation, covered a wide range of aspects of orchidology. This volume gives a general account of the programme and proceedings of the conference and includes all the papers delivered during its thirteen sessions.

The Conference was given an excellent send off by Dr. W. T. Stearn of the British Museum (Natural History), who entertained the members with a scintillating and highly humorous account of the development of orchidology from classical times up to the present day. Following this, each session dealt with some special aspect of the subject or with one of the more important groups of cultivated orchids. The former include such diverse subjects as culture methods for amateurs, the principles of orchid nutrition, the ecology of orchids, diseases and pests, aspects of the orchid trade, the classification of orchids, growing orchids in rooms, and orchids in botanical gardens. The papers on cultivated orchids deal with the genera *Cattleya, Vanda, Phalaenopsis, Cymbidium, Dendrobium, Cypripedium, Odontoglossum, Miltonia* and their close allies. These last-named papers include accounts of the latest methods of cultivation, progress in breeding and criteria used in judging. Altogether there are forty-eight papers and these taken together provide an adequate cross-section of the various activities which are being pursued to-day with respect to this remarkable and entrancing family.

The general format of the book is pleasing, the print being easy to read. There are ten excellent coloured plates of orchids which gained awards in the Royal Horticultural Society's Chelsea Show held just before the Conference and nearly thirty monochrome illustrations. In addition many of the papers contain illustrative text-figures. Altogether this is a book which everyone interested in orchids will require, containing as it does many of the latest ideas bearing on the cultivation, breeding and classification of these plants.

V. S. SUMMERHAYES

Advances in Agronomy, Vol. 12

Edited by A. G. Norman. (Prepared under the auspices of the American Society of Agronomy.) Pp. xi+464. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1960.) 12.50 dollars.

THE present volume fully maintains the standard set by recent issues of *Advances in Agronomy.* It contains eight reviews of United States work each of which is long, detailed, exhaustive and dull. Research papers are often summarized in single sentences and more-or-less contrary findings by different authors are recorded consecutively with serene impartiality and little or no critical comment.

Of the articles in this volume, that by Rich and Thomas on the clay fraction of soils is unusual in including many references to work done outside the United States and in dealing with recent work—real 'advances'. "Fertilizers in Forestry" (Stoeckeler and Arneman) also makes a good attempt at bringing together work done in many countries. Two papers on soya beans (81 pages in all) leave the reader with the impression that a great deal of research on this crop is proceeding, but that very little of it is likely to lead to increases in yield before 1980.

"Water Infiltration into Soils" (Parr and Bertrand) catalogues many fascinating pieces of apparatus and indicates the difficulties in measuring infiltration in the field. Fergus and Hollowell give a good historical account of red clover and research in progress on it; this paper includes a good account of husbandry in the field.

Of the rest, the paper on "Agronomy in the South-west United States" seems misnamed—it describes the agriculture of the area; the paper on grass and legume seed-production and testing omits all reference to the inoculation of legume seed, and in a long section on diseases dismisses bacteria, viruses and nematodes in one sentence. G. V. Dyke

Flora of Peru

By J. Francis Macbride. (Botanical Series, Vol. 13, Part 5, No. 1.) Pp. 536+ii. (Chicago: Field Museum of Natural History, 1959.) 8.50 dollars.

Mr. MACBRIDE continues his *Flora of Peru* with a volume devoted to the Araliaceae, Haloragaceae and a number of difficult gamopetalous families such as Ericaceae (including Vacciniaceae), Myrsinaceae, Ebenaceae, Gentianaceae, Apocynaceae and Convolvulaceae. The accounts of important genera such as *Buddleia* and *Strychnos* are also here. This work, as before, is a useful compilation as a basis for monographic work by specialists, and the author is an adept at pointing out the "interlocking characteristics" of the "species groups at present designated as genera" in some families. His numerous remarks in this vein force one to the conclusion that it is no good having 'specialists' in some of these families unless they have first-class brains and time for concentration on a wide survey over a long period. Mr. Macbride is old-fashioned enough to use the illegitimate name *Erythraea* for *Centaurium*, and he ignores the name *Gentianella* for a segregate genus covering the many Andine gentians, which he maintains in *Gentiana*. On p. 152, *Samolus Valerandi*, to which the South American *S. floribundus* Kunth is reduced, is unfortunately misprinted *S. Verlanderi*.

N. Y. Sandwith

The Atomic Problem

A Challenge to Physicists and Mathematicians. By Lancelot Law Whyte. Pp. 56. (London: George Allen and Unwin, Ltd., 1961.) 7*s*. 6*d*. net.

The author calls for a drastic revision of the principles of physics in order to find answers to unsolved problems in that branch of science. In particular he wishes to retain the "principle of atomism" and to discard "linear co-ordinate systems, dimensional parameters, two-entity interactions and time-invariants". Many of his propositions could be interpreted in different ways, but there is an unambiguous demand for a theoretical deduction of the fine structure constant; there is also a clear request for including irreversibility in the basic laws of the new physics. While not attempting to substantiate his programme the author expresses the hope that others might follow his directives.

The fundamental principles of a science are due for revision if unsolved problems prove *insoluble*. In contemporary physics this situation does not arise: existing theories have neither spent their force nor are they tied to any rigid preservation of all their details. Current attitude to irreversibility belongs to the best secured domains of physics. The problem of the fine structure constant will attract more attention than at present if it acquires any direct experimental implications. Perhaps the author believes that theoreticians are a complacent lot; they still continue to interpret new discoveries in terms of old theories unless incompatibility is clearly recognized. It would not be wise to prophesy now which of the author's propositions will materialize in a future revision. R. Eisenschitz

An Introduction to Infinitely Many Variates

By Prof. Enders A. Robinson. (Griffin's Statistical Monographs and Courses, No. 6.) Pp. 132. (London: Charles Griffin and Co., Ltd., 1959.) 28*s*.

The word 'Variates' in the title means 'random variables'. The first twenty pages give an account of probability theory as a normed measure over an abstract space. The next fifteen discuss limit theorems: followed by sixteen on Hilbert space and linear operators. These latter ideas are used in twenty pages on the spectral representation of stochastic processes and thirty pages on stationary processes. There is a large and useful collection of exercises. There is an extensive use of advanced mathematical ideas and notations, but practical problems are not entirely ignored (for example, section 7.9 on wavelet theory).

The monograph has been designed to give undergraduates an introduction to advanced techniques early in their statistical training. To my mind it is too condensed for this, and makes too many errors. Students at this level will not be familiar with the Radon-Nikodym theorem, and therefore will not know that it is stated wrongly on p. 13—nor the inversion theorem on p. 30—nor the definition of continuity on p. 19. But the book could be valuable for readers who can spot such mistakes and require a brief introduction to limit theorems and spectral analysis. The book would have been better had it been more carefully written and had it not been so curt, for the material is well organized. D. V. Lindley

Chemistry of Carbon Compounds

A Modern Comprehensive Treatment. Edited by Dr. E. H. Rodd. Vol. 4, Part C: Heterocyclic Compounds. Pp. xviii+1465–2201. (Amsterdam: Elsevier Publishing Company; London: D. Van Nostrand Company, Ltd., 1960.) 130*s*.

With Volume 4 of this work the section on heterocyclic compounds is complete and the whole project draws near to its conclusion. This volume continues the systematic treatment of six-membered ring systems containing two hetero-atoms, proceeds to those with more than two and hence to seven-membered and larger heterocycles. Separate chapters present excellent accounts of azine dyes, of purines, of nucleosides and nucleotides and of pteridines. About half the volume is devoted to a survey of alkaloids, largely written by A. R. Pinder, with contributions by K. W. Bentley and G. F. Smith. They and the other contributors are to be congratulated on a high order of achievement. The more familiar terrain and the outer reaches of the subject are charted with competence and lucidity that belie the magnitude of the tasks involved.

This is no mere cataloguing, but a genuine appreciation and appraisal of the state of these chemical topics, close to the date of publication. Once again a team of authors and a redoubtable, indefatigable editor have put the world of organic chemists in their debt. James D. Loudon

THE CROSS-ANTENNA OF THE PROPOSED BENELUX RADIO TELESCOPE

By Prof. W. N. CHRISTIANSEN* and Dr. J. A. HÖGBOM

Benelux Cross-Antenna Project, Leyden

SEVERAL years ago, C. L. Seeger of the Netherlands Foundation for Radio-astronomy proposed[1] that a very large radiotelescope of the Mills cross type[2] should be built in Europe for high-resolution studies in radio-astronomy. The main feature of this radio telescope was to be its resolving-power of one minute of arc at a wave-length suitable for observations of discrete radio sources and of the structure of nearby galaxies.

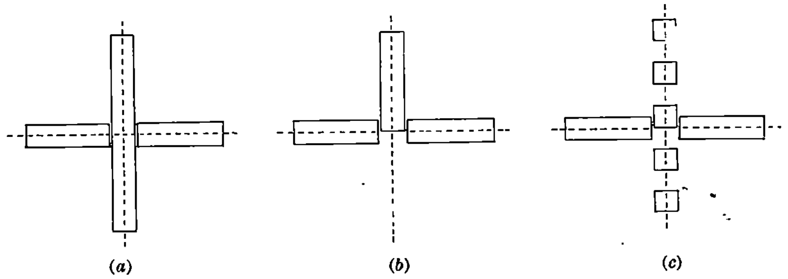

Fig. 1. Antennæ with similar beam-width. *a*, A Mills cross; *b*, a T-antenna; *c*, a displaced-centre grating cross

The dimensions of this antenna would be so large that it would be necessary to distribute radio-frequency amplifiers along the antenna in order to overcome a loss of sensitivity which would be introduced by severe attenuation in the transmission lines between antenna and receiver. It was suggested that these amplifiers could be made to serve an additional useful purpose, by using them in a way similar to that in the large grating-interferometer at Nançay in France[3]; the input of each amplifier would be connected to a small section of the antenna and the outputs of the amplifiers would be split into n separate channels. The output of each channel would then be correctly phased and combined with the outputs of one channel of each of the other amplifiers. The result of this is that each channel could be made to respond to radio emissions from a slightly different direction in the sky, so that with no loss in sensitivity the antenna would have n separately usable beams instead of one. By this means observing time can be reduced by a factor of n; the necessity for this is obvious when it is realized that with a

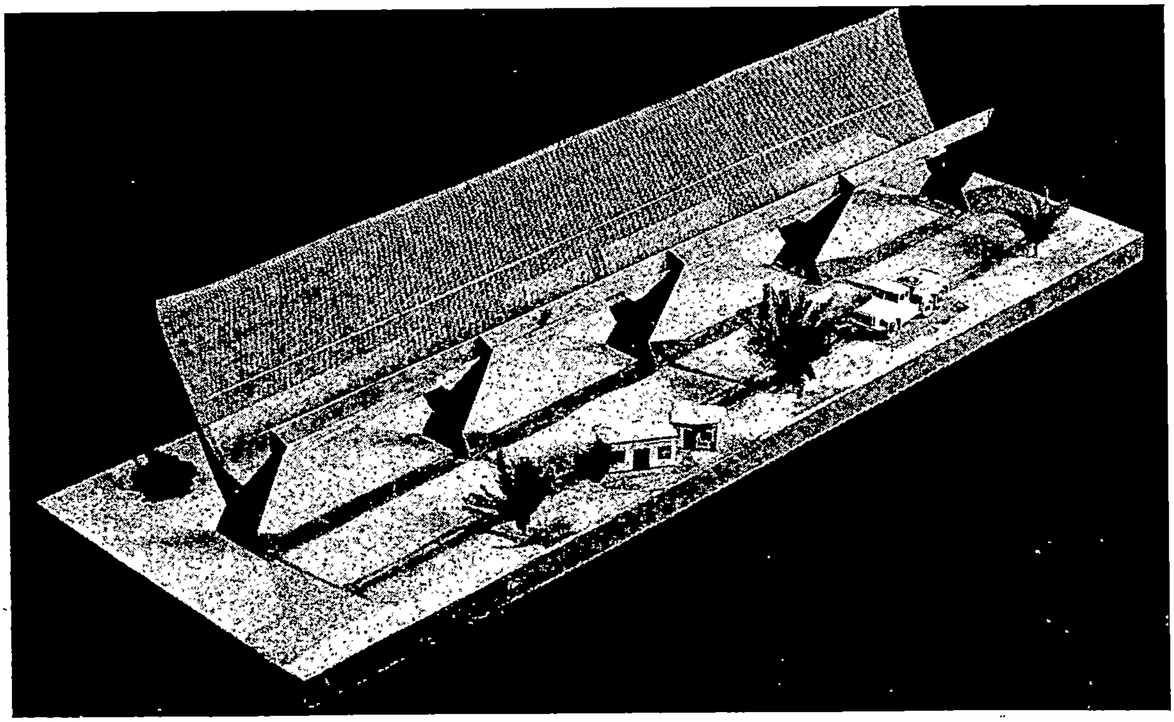

Fig. 2. A model of one section of the north–south array of the proposed Benelux cross. The dimensions are 15 m. × 85 m.

---

* On leave from the University of Sydney.

single 1′-arc beam, approximately 50 years would be needed to complete a survey of the sky.

As a result of this proposal, a committee with Netherlands and Belgian representation was set up under the chairmanship of Prof. J. H. Oort to investigate the possibility of building such an instrument. The committee is known as the Council of the Benelux Cross Antenna Project. A report was prepared[4] specifying the wave-length to be used (73 cm.), the size (600,000 m.^{2}), the resolving power (1′ arc) and emphasizing the necessity of designing the antenna to have very low response outside the region of the principal response.

Funds for the design of the large Cross Antenna were provided jointly by the O.E.E.C. Committee on Scientific and Technical Personnel, the Netherlands Organization for Pure Research (Z.W.O.) and the Belgian Ministère de l'Instruction Publique.

Recently, we have prepared a report[5] in which a suitable design for the cross-antenna of the Benelux radio telescope is submitted; we shall describe its main features here, since some of these are novel and may be of use to those interested in the planning of other large radio telescopes.

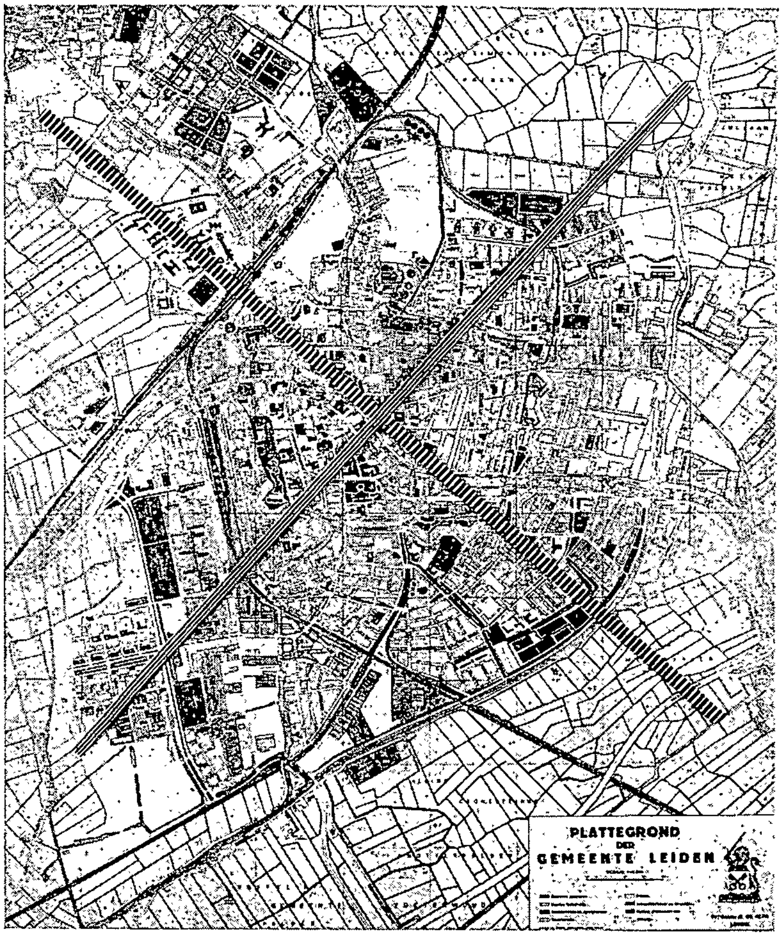

Fig. 3. Suggested arrangement for the 5,000 m. × 5,000 m. Benelux cross-antenna. The antenna is superimposed on a map of Leyden to provide a scale

The original Mills cross[2], which had a beam-width of 50′ arc, consisted of a north–south and an east–west array of parallel dipoles; the pencil-beam response of the antenna was produced at the intersection of the fan-shaped responses of the two arrays by a multiplication process first used by Ryle[6] in radio-interferometry. The angle of elevation of the principal response of the cross could be changed by readjusting the phases of currents transmitted to the receiver by the individual dipoles of the north–south array; this changed the angle of elevation of the fan beam of the north–south array and hence the direction in which this beam intersected the beam of the east–west array. The scanning of the sky in hour-angle was produced by the rotation of the Earth. One feature of this cross was that the 'steering' of the antenna response was effected without mechanical movement of any part of the antenna.

For an antenna which has an aperture (in square wave-lengths) three or four orders of magnitude greater than that of the first Mills cross, the use of simple fixed dipole arrays is impracticable, since the number of dipoles required is about 10^6–10^7 and the number of separately phased groups of dipoles is 10^4–10^5. The number of active elements in the antenna may be reduced by using parabolic reflecting surfaces; but these, except in special cases, must be capable of being tilted to allow the direction of the principal response of the cross-antenna to be varied.

In two of the large Mills crosses which are being built or planned, one in the U.S.S.R. and one in Australia[7], line arrays of dipoles are backed by cylindrical parabolic reflectors. For the east–west array these reflectors are capable of movement about the long axis of the array; in the north–south array the reflector is fixed, and the direction of the fan-beam response of the arm is varied by phase-changes in the dipole-array, situated in the line-focus of the parabolic reflector, in a similar fashion to that of the original Mills cross.

For the projected Benelux cross, which would have dimensions several times greater than these two crosses, such an arrangement would involve the separate phase-adjustment of more than 10^4 closely spaced elements for each change in declination of the antenna response. We have tried, therefore, to find a solution to the problem that will involve the phase-adjustment of only a limited number of elements. If the north–south array is divided into sectors each of which can be tilted in declination, the number of elements requiring separate phase adjustment can be reduced by a factor of about 100; moreover, the phasing difficulties are considerably reduced because the coupling between the sections can be made negligible. The difficulty which is introduced by this arrangement, however, is that each element tends to 'shadow' its neighbour as the array directed away from the zenith. If we separate the elements to avoid this shadowing, then multiple antenna responses are found; these are similar to those of a grating interferometer[8], and for the purposes for which the Benelux cross is designed, highly undesirable. We have found, however, that it is possible to overcome these difficulties.

It is known[9] that one of the four arms of a cross-antenna (Fig. 1*a*) can be removed without restricting the spatial harmonic response of the antenna, or in other words, without increasing the beam-width of the principal response of the antenna.

If, in such a T-antenna (Fig. 1*b*), we remove alternate sections of the asymmetrical arm, and place them on the opposite side of the antenna, as shown in Fig. 1*c*, then we have a cross-antenna in which one array is broken up into spaced sections. The unwanted grating-responses of this arm have been suppressed, however, by the displacement of its centre with respect to the centre of the continuous array. With this arrangement, we can now tilt the sections of the north–south array over a wide range of angles without having one section fall in the shadow of its neighbour.

It will be seen that the antenna design just described does not provide a complete solution to the problem, since the proportion of the north–south arm which is filled by the antenna elements changes with the angle of elevation. This, and non-uniformity of illumination of the elements of the north–south array, will produce the effect of a 'ripple' along the north–south array and unwanted secondary responses of the antenna will appear.

The unwanted responses can be reduced or eliminated if the response of the east–west array is made negligible in these directions, since the cross response in any direction is proportional to the product of the responses of the east–west and north–south arrays. One way to do this would be to make the elements of the east–west array larger (in the north–south direction) than those of the other array. Since there are considerable advantages in making the elements of both arrays similar, a better solution is to break up the east–west array into two parallel arrays, spaced so that zero responses fall in the direction of the principal unwanted 'ripple' responses. Alternatively one may break up the east–west array into four parallel rows instead of two, and this may have economic advantages; the suppression of unwanted responses, moreover, is slightly superior to that of the two-row arrangement.

With this design, in which all elements are similar and have the same orientation, it is obviously possible to use the very economical frame and stretched-wire type of construction for the parabolic cylindrical reflectors[9]. A photograph of a model of such an antenna, with an off-aperture line-feed designed for accessibility and to reduce unwanted responses, is shown in Fig. 2. Fig. 3 shows the general arrangement of the cross-antenna in which four lines of parabolic reflectors, each 5,000 m. × 15 m. in aperture, are used for the east–west array, and 240 elements, each 85 m. × 15 m., make up the north–south array. The performance of this cross-antenna has been calculated, and it has been found that the discontinuous structure of the north–south array does not produce any significant deterioration in performance when compared with the theoretical performance of a uniform structure. On the other hand, the number of places at which current phases have to be changed is relatively small, and these can be individually monitored, so that one might hope to keep a more accurate phase control than would be possible with a uniform structure in which very large numbers of elements are involved.

ELECTRICAL PROPERTIES OF ORIENTATED LIPID ON A BIOLOGICAL MEMBRANE

AN ELECTROSTATIC DIFFUSION BARRIER AND ION PUMP

By Dr. J. W. L. BEAMENT

Agricultural Research Council Unit of Insect Physiology, Department of Zoology,
University of Cambridge

THE layer of lipid over the cuticle of insects is said to contain an orientated monolayer of lipid molecules on a substrate of the tanned lipoprotein of the cuticle membrane[1-3]. It is this monolayer which is believed to provide both the extreme impermeability of the cuticle to water[2-4] and also the unusual wetting properties which the surface may exhibit[4-7]. It has been suggested that the polar ends of the lipid are strongly attracted to the tanned lipoprotein, so that the monolayer remains stable even when, as in aquatic insects, the non-polar ends of the lipid are in contact with liquid water for long periods[5]. Now it is known that certain types of monolayer film at an air/water interface may be associated with surface potentials[8]; but as such films become unstable if a further aqueous phase is brought into contact with their outer surface, investigation of their electrical properties is largely confined to the use of an air-electrode in the form of a radioactive source. If, however, the insect cuticle does have such a monolayer, it should produce an electric potential; since that monolayer is stable in the presence of aqueous phases on either side, then those properties should be readily measurable. Investigation of the electrical properties of the membrane therefore presents a means of testing the hypothesis that a monolayer occurs, for that hypothesis has been based entirely on the study of the relationship between the

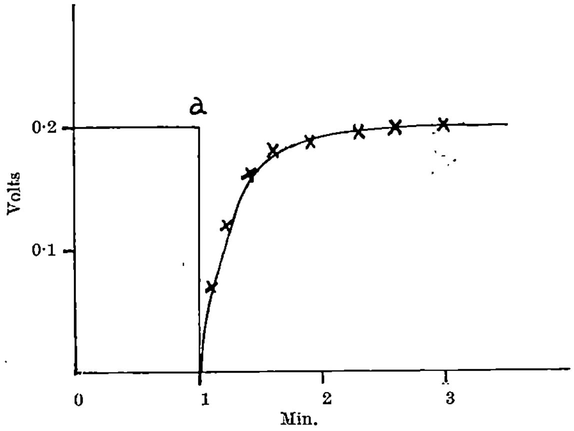

Fig. 1. Open-circuit voltage across a membrane preparation short-circuited for 5 sec. at *a*

membrane and water: either through measuring permeability or surface adhesion.

Electrostatic Potential across the Membrane

A membrane may be prepared from the integument of the cockroach *Periplaneta* by removing the cellular epidermis. When this membrane is arranged so that both sides are in contact with 1 per cent solutions of sodium chloride, there is a potential difference of the order of 200 mV. across the membrane, the morphological outside being positive with respect to the inside. Ten such membranes have given values between 170 and 235 mV., measured by a valve voltmeter of input impedance greater than 10^9 ohms. This potential depends on the grease (lipid) layer of the cuticle being intact, and can be destroyed by lipid solvents and by detergents. A potential difference of the same value is present across a cuticle membrane from which excess superficial grease has been removed by washing in the surface of clean water[2,5], that is, across a membrane believed to have only the orientated monolayer of grease on its surface. A similar electrical phenomenon has now been obtained with an artificial membrane coated on one side with grease from a cockroach (see below).

Using either a membrane with a natural thickness of grease (0·25μ) or with a monolayer, and with 1 per cent solutions of sodium chloride on either side, a small current will flow through a resistance connected between electrodes which dip into the solutions. If an ammeter of low resistance is used, a current of about 5 μamp. flows momentarily, and the potential across the electrodes falls very rapidly to an immeasurably low level. However, if connexion between the electrodes is then broken (except for the electrometer measuring the inter-electrode voltage) the original potential difference of 200 mV. reappears in the course of a few minutes. This process of recovery is exponential in form (Fig. 1), and by some 5–10 min. after 'shorting' the full potential difference has apparently been regained. The process of 'shorting' the electrodes may be repeated indefinitely—on each occasion the open-circuit potential of 200 mV. is re-established: one preparation has continued to behave in this fashion for 110 days with several hundred such treatments. But it is essential to maintain fresh solutions on both sides for recovery to be complete after short-circuiting in this fashion. If a high resistance is connected between the electrodes, then the potential difference across it falls rapidly to an intermediate value (for example, 50 mV. across a 22-M.ohm resistance in a typical experiment), and provided solutions of 1 per cent sodium chloride are maintained on both sides of the membrane, current continues to flow through the resistance. If the solutions on each side of the membrane are not maintained by perfusion, and the electrodes are connected through a resistance, the potential difference falls slowly. If the two electrodes are directly connected, and the preparation is left for several hours without perfusion, when the circuit is then opened, a lower potential difference than 200 mV. appears across the electrodes in the following few minutes.

Movement of Ions

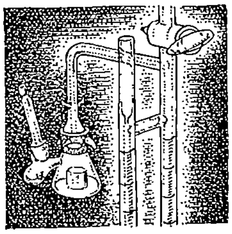
In a typical experiment, which started with two identical solutions of 1 per cent sodium chloride on either side of a membrane initially developing 205 mV. potential difference, the electrodes were short-circuited for 24 hr., and the circuit then opened; the potential difference was 90 mV. It was found that there was a difference of 2·1 *p*H units between the two sides—the solution against the morphological inside of the membrane having become more acid. A difference of 2·1 *p*H units between two solutions corresponds to 120 mV. This, added to the 90 mV. remaining across the electrodes, gives 210 mV., which is, within the experimental error of the methods used, in agreement with the initial open-circuit voltage of 205 mV. across the membrane at the start of the experiment. If the two sides of the membrane are then perfused with fresh 1 per cent sodium chloride solutions, the original potential difference of 205 mV. may be obtained. It is clear from this and other similar experiments that ions are transported across the membrane to produce two different solutions when electric current flows through the membrane, that is to say, the device will transport ions against a concentration gradient. Stable equilibrium, in the sense that no potential difference may be measured between the two sides of the membrane, is reached when the concentration potential between the solutions on either side counterbalances the electrostatic potential on the membrane; but this is reached only after several days.

Origin of the Electrostatic Potential in the Membrane

Using a membrane with a thick layer (0·25μ) of grease on it, and 1 per cent solutions of sodium chloride on both sides, a voltage may be applied across the preparation by connecting a suitable generator, such as a battery. If the membrane is momentarily subjected to an externally applied potential difference of 6 V. of the same polarity as the 200 mV. naturally found on the membrane, an open-circuit potential difference of about 4 V. can immediately afterwards be measured. These excess voltages are here called 'over-charge'. If the applied voltage be of opposite polarity to the natural potential difference of the membrane, then the open-circuit potential difference immediately after treatment is found to be reversed (reverse-charge). Intermediate values of over-charge and of reverse-charge potentials can be produced by using smaller polarizing

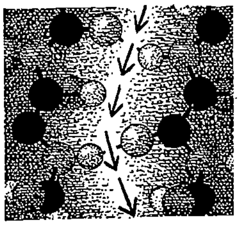
IT HAPPENED THIS MONTH...

a glance at yesterday in relation to today



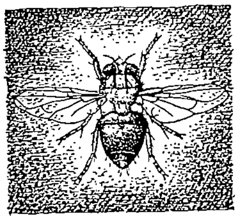
IN JULY—(1873)—Joseph Lister reviews a series of experiments supporting the germ theory of fermentation. This work utterly disproves the rival oxygen theory and shows all reported instances of spontaneous generation have been due to faulty experimentation. There is no evidence that any chemical possesses the one characteristic that distinguishes all true fermentation—self-propagation. However, it has been shown that emulsin, a peculiar albuminous principle existing in sweet and bitter almonds, can break up ten times its weight of amygdalin. "In this sense, then, as intervening between the growth of organisms and the resultant decompositions, the theory of chemical ferments might be welcomed as a valuable hypothesis."[1]

Within a short time, this theory became fully established, and the chemical ferments elaborated by yeast became known as enzymes. It has taken considerably longer for the self-propagating properties of certain chemicals to become a major subject of research. Currently the relation of the nucleic acids to genetic duplication and virus replication has become one of the focal points of research. Whether you are concerned with enzyme action or nucleic acid chemistry, the biochemical intermediates available from Schwarz BioResearch—plain or labeled with C^{14}, H^3, S^{35}, or N^{15}—may provide useful tools for your research.



IN JULY—(1933)—a report from the Lister Institute (London) considers the effect of proteolytic enzymes on the oxytocic hormone. Gulland and Macrae[2] find that two commercial trypsin preparations inactivate this hormone at widely different rates. A comparison experiment using quantities with equal tryptic activity clearly indicates that the inactivating enzyme is not trypsin. Nor is it a papainase, arginase, or prolinase. Aside from the fact that this inactivating enzyme accompanies proteolytic enzymes, there is no evidence adduced here that the oxytocic hormone contains peptide linkages.

Twenty years later, du Vigneaud received the Nobel prize for investigations which established the polypeptide structure of oxytocin through amino acid analysis, systematic degradation, and chemical synthesis. Chemists at the Yeda Research and Development Company at the Weizmann Institute (Israel) have synthesized a wide variety of peptides, polyamino acids, and intermediates for peptide synthesis which are distributed by Schwarz BioResearch. A special catalog listing these compounds is available upon request. Write for a quotation on your individual requirements.



IN JULY—(1953)—the Journal of Histochemistry and Cytochemistry discusses the function of the sarcosomes of insect flight muscle. It is suggested that these small spherical bodies play a role similar to that of mammalian mitochondria. ATP is synthesized in the sarcosomes by oxidative phosphorylation, and the energy-rich phosphate is made available for actomyosin contraction by diffusion into the adjacent muscle fibrils. Following contraction, ADP diffuses back into the sarcosomes (the sarcosomal membrane being impermeable to AMP), and the cycle is repeated.[3]

Adenosine phosphates have long been an important specialty in the Schwarz BioResearch line. We supply the various isomers of adenylic acid, as well as ADP, adenosine 3′:5′-cyclic phosphate, adenosine 5′-phosphoramidate, and several grades of ATP. The 5′-mono-, di- and tri-phosphates of guanosine, uridine and cytidine have recently been added to our list. Many of these compounds have been radiolabeled and all are listed in our regular catalog. MAXTA

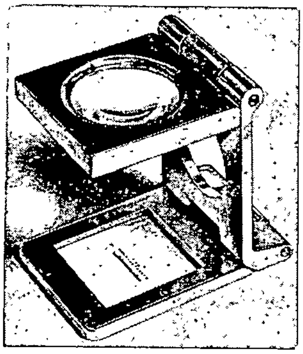
FOLDING MICROMETERS



Here at last is the ideal pocket instrument to give you really accurate measurements. A clear cut and robust graticule is built into the base of a folding magnifier so that the image can be placed in contact with the object being measured. An accuracy of measurement down to 0.002″ is comfortably achieved.

A large variety of patterns is available to suit most requirements, but above all this micrometer is for on-the-spot measurement be it in drawing office, laboratory or on the factory floor.

Full particulars and prices gladly sent on request.

The Scorah **OXY-COAL GAS BLOW PIPE**

specially for working BOROSILICATE GLASSES (Pyrex, Phoenix, Hysil, etc.)

- Five jets and central pilot light — flame size selected INSTANTANEOUSLY.
- Rotating turret head for easy jet selection.
- Auxiliary supply of oxy coal mixture for hand torch.

Minimum oxygen consumption
Maximum economy

A modern oxy-coal gas blow-pipe of sturdy construction evolved through years of practical experience in glass manipulation. A nearly silent flame from pin point to one capable of working 100 mm. tubing at a flick of the turret. To the inexperienced it gives confidence, to the experienced it is an assurance of efficiency and successfully completed work. A unique instrument for the research laboratory or workshop. Send for Leaflet BP/N2.

Obtainable only from

Price **£25.0.0**

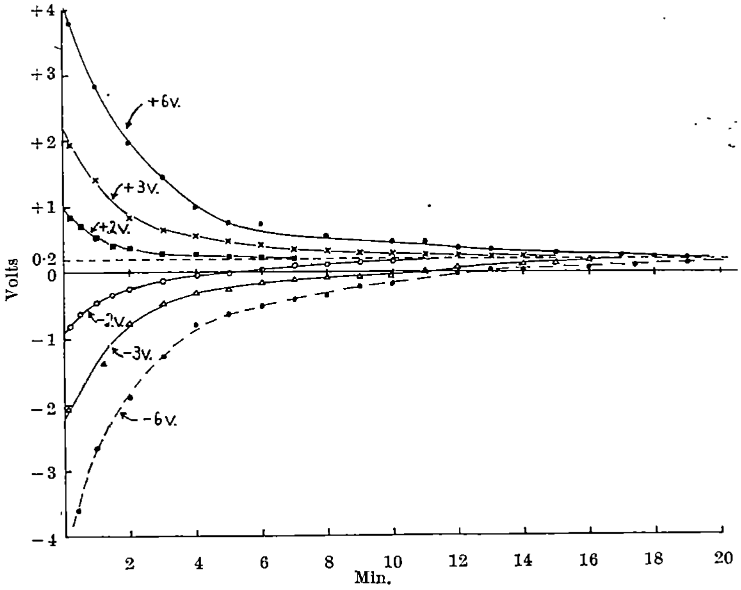

Fig. 2. Decay of over-charge voltages, and of reverse-charge voltages across a thickly greased membrane under open-circuit conditions. Labelling figures on each curve show the potential difference and polarity of the generator initially applied across the membrane to create the over-charge or reverse-charge. The untreated preparation has 200 mV. across it

voltages (Fig. 2), but potential differences in excess of 6 V. applied to the preparation will not raise the open-circuit voltage above 4 V. Both over-charge and reverse-charge potentials decay under open-circuit conditions over a period of about 20 min. to give the normal potential difference of 200 mV. (Fig. 2). ('Open-circuit' here means either with the valve voltmeter continuously attached to the electrodes, or momentarily attached to obtain potential difference values.) If, during the decay process, the electrodes are momentarily connected by a low resistance, the potential difference between electrodes falls to a very low level just as with a normal preparation (Fig. 1). And like a normal preparation, over the following minutes, the over-charged, or reverse-charged, preparation will produce a potential difference between electrodes when returned to open-circuit conditions (Fig. 3). However, the potential difference which reappears is that which the preparation would have reached by decay, if it had not been short-circuited. In other words, the process of recovery of the normal potential difference from conditions of over-charge or of reverse-charge is independent of the load placed across the membrane.

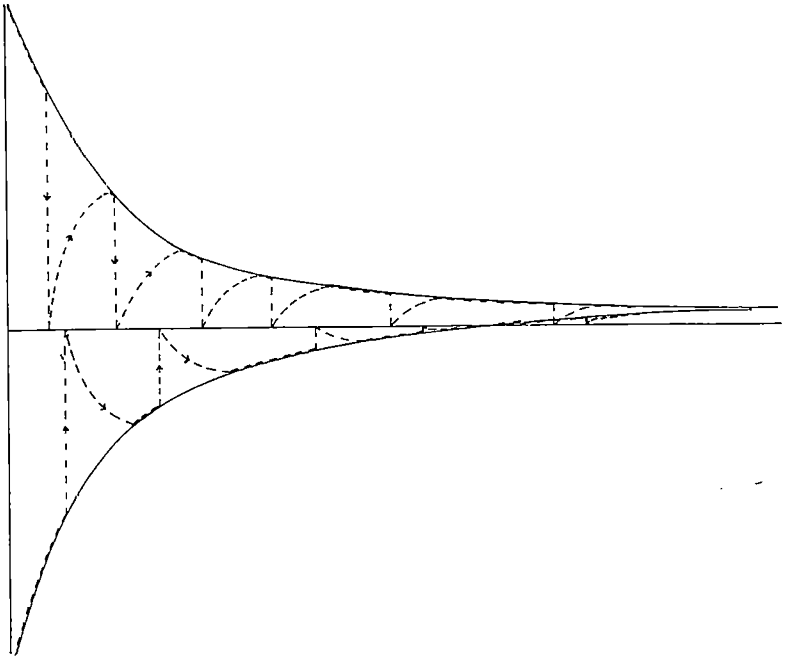

Fig. 3. Semi-schematic. The dashed line shows the form of recovery of the preparation of Fig. 2, over-charged or reverse-charged by 6 V., when repeatedly short-circuited momentarily during its decay. The natural decay is shown by the unbroken curves

However, when an external voltage source is applied across a water-washed membrane (which has only the basal monolayer on it), no such temporary over-charged or reverse-charged states can be produced. The excess potential difference created on the thickly greased membrane must therefore be associated with the grease above the monolayer. When an artificial membrane is used, covered on one side with a thick layer of grease, or with a monolayer only, little if any potential difference can at first be measured when the membrane is mounted and perfused with 1 per cent solutions of sodium chloride on both sides. A small polarizing voltage (0·5–1·0 V.) applied across the membrane will suffice to produce a standing potential difference of about 200 mV. from this preparation, and then it will behave almost identically to a membrane taken from a cockroach. If the grease is thick, temporary overcharge phenomena can similarly be obtained. However, if a polarizing voltage of reverse polarity is applied to an artificial membrane which has only one monolayer on its surface, then a relatively stable potential difference of about 200 mV. occurs across the preparation, with reverse polarity, that is, with the greased side of the membrane negative to the ungreased side. The best artificial membranes so far produced do, however, lose their open-circuit potentials in the course of a few days, despite maintaining fresh 1 per cent solutions on either side. They can, however, be repolarized by an externally applied voltage at any time.

It is useful, in explaining these phenomena, to make reference to the phenomenon of the 'electret'[9] as well as to the surface potentials of monolayers at air/water interfaces. An electret is a material having a permanent electrostatic state, which is analogous to the permanent magnetic moment of a magnet. It has been known for many years[10-12] that a permanent electrostatic moment can be produced in a block of a suitable wax by melting it and allowing it to solidify in a powerful electric field; it is perhaps significant in the present context that beeswax is among the materials most suitable for making electrets, and it has indeed been suggested that it is the long-chain primary alcohols (such as are believed to comprise insect waxes[3,13]) which are essential components in electret-forming waxes. Although controversy still surrounds the explanation of some electretic phenomena in physical and theoretical terms[14-16], it would seem most satisfactory to assume that electron-displacement towards the polar group along the long chain of the alcohol molecule gives it its electrostatic moment. Crystallographic evidence has been advanced to support the idea that, in a hard wax electret, crystallites of wax are all aligned, whereas in normal wax they are randomly arranged, and that such alignment has been brought about in the molten wax under the influence of the applied electrical field, with the result that all the electrostatic moments are fixed, orientated, when solidification occurs[16]. A hard wax electret is virtually permanent. (Swann[17] suggests that slow thermal derangement of the domains in an electret will occur, producing degeneration, but that the half-life of the system is several years).

So far as the monolayer of grease on cockroach cuticle is concerned, the aligning force acting on the polar molecules is the high adhesion of the polar groups to the tanned lipoprotein substrate of the cuticle surface. Since this will also align the electrostatic moments of the molecules, an electret voltage would be expected to appear. It is interesting that a potential difference of 200 mV. across the probable thickness of the grease monolayer is the equivalent of an electrostatic gradient of 20,000 V./cm., which is precisely the highest electrostatic gradient quoted by several investigators of hard wax electrets[14,15,17]. Now according to the theories proposed from experiments on water permeability and surface properties[2-5,7], the bulk of the grease overlying the monolayer on a natural insect cuticle is not molecularly organized—on the cockroach it is a viscous fluid, and thermal agitation will ensure that the molecules are randomly arranged. Hence both the natural cuticle of the cockroach, with its thick grease, and also the cuticle washed by a water surface until only a monolayer remains, would be expected to produce the same electretic potential difference corresponding to one monolayer—which is found experimentally. If, on the other hand, an electric field is imposed on the thick grease, temporary alignment of all the grease molecules will be produced, and immediately after the application of such a polarizing field, the phenomena of over-charge or of reverse-charge, reported above, appear. The decay of these higher-energy states of induced molecular alignment is a direct consequence of the thermal derangement of the molecules in the thick grease (which may be from a normal or from an inverted orientation, depending on the polarity of the polarizing voltage which was applied); but the basal monolayer cannot be so deranged, and the preparation returns to a potential difference of 200 mV., regardless of whether it is short-circuited or not. The decay cannot, in fact, be influenced unless some further energy source is introduced into the system.

In a monolayer preparation, over-charge and reverse-charge potentials cannot be induced, because there is no thick grease to align. On the artificial membranes so far used, it is clear that the adhesion of the polar groups in the grease to the substrate is by no means as great as it is to insect cuticle. A combination of thermal agitation and electrical strain will thus prevent the formation of a good monolayer *ab initio*; but in an appropriately polarized electric field applied across such a membrane, a monolayer can be aligned—or indeed an inverted monolayer can apparently be stabilized. When this monolayer is inverted there are some indications that the surface adhesion of the monolayer to water is greatly increased, so that we have a direct confirmation of the theory of monolayer inversion and the production of hydrofuge surfaces already proposed[5]. However, it is seen from the experimental results cited here that, on an artificial membrane, the polar attractions to the substrate are not sufficient to maintain the monolayer against thermal and electrical strain, and it very slowly decays, whereas the structure on the more efficient substrate of cuticle is seemingly permanent. This adds to the conclusion already reached on different grounds[3,6] that considerable energy is needed in the construction by the insect of its monolayer.

Energies of the Ion Pump

It must be clearly understood that a monolayer, with its distribution of charge, does not represent a 'battery' or source of energy, any more than a hard wax electret does. In the case of the hard wax electret, current will flow temporarily through a wire connecting two plates applied to the two sides of the block of wax. If the plates are repeatedly removed and replaced, current may repeatedly be drawn: the energy for this electric power is put into the system by the process of applying and removing the plates. In the case of the cell, made up of a permanently charged membrane, with identical solutions on either side, current can only be obtained in the external load for so long as the two solutions are maintained. Consider the well-known phenomenon of the diffusion or concentration cell (Fig. 4*A*). A potential difference is generated between two solutions of different composition separated by a membrane which is electrically inert, but through which components of the two solutions may diffuse. The potential difference between the two solutions is determined by the difference between the composi-

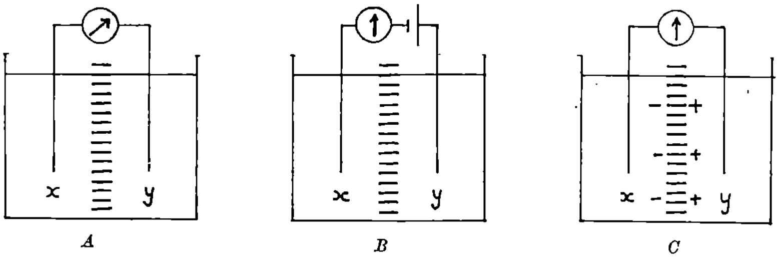

Fig. 4. See text

tions of the two solutions; it disappears when the solutions have become the same through diffusion, and the system has reached a state in which there is no thermodynamic difference across the membrane. However, if the changes in the two solutions, due to diffusion through the membrane, are countered by perfusing the two sides of the membrane with their respective original solutions, the potential difference across the membrane can be maintained indefinitely; energy is introduced into the system in removing the products of diffusion.

If a source of potential difference (not of energy) is inserted into the leads connecting the electrodes of such a cell (Fig. 4*B*) current does not flow in the external circuit when the two solutions are at compositions which are not identical, but which are such as to generate a potential difference equal and opposite to that of the introduced source of potential. This represents the equilibrium state in which energy cannot be derived from the difference between the solutions. However, this situation is electrically identical to one in which such a source of potential is introduced at another point in the circuit—across the membrane (Fig. 4*C*). It follows that if identical solutions are placed on both sides of a membrane with an electrostatic potential across it, the composition of these solutions will tend to change until they establish an electric potential exactly compensating that on the membrane, and that this condition will represent thermodynamic equilibrium in the system. It further follows that, in the device described in the early part of this article, the source of energy for the continuous flow of current through an external load is provided by the perfusing solutions of 1 per cent sodium chloride, in displacing the concentration difference which the membrane is endeavouring to establish on either side of itself.

The biological consequences of this system cannot as yet be fully foreseen. An electrostatically charged monolayer of lipid is capable of maintaining two solutions of different composition, concentration, *p*H, etc., on either side of itself, without the expenditure of energy, that is, a thermodynamic device of great biological advantage; it must be remembered that this it can only do because of the enormous amount of potential energy stored in the monolayer, both in its orientation order and also in its bonding to the protein substrate. Maintenance is not, however, necessarily a static matter; if the solutions on either side change from such compositions as to offset the membrane potential, ions may be transferred to counter that change. The membrane may, therefore, be the integral part of a biological 'ion pump'; the energy for this pump is not derived from any 'carrier' used in the transport process, but is a direct consequence of the organization of the membrane itself. Biologically speaking, the energy for using the pump might be provided by the manipulation of the concentrations of materials on either side of the monolayer. It is appreciated that, according to current ideas, cell membranes contain a bimolecular leaflet of lipid, rather than a monolayer, but it would be necessary only for there to be a net electrostatic field from the algebraic sum of the moments of the monolayers comprising the leaflet, for the system outlined in this article to operate; of course, across a complex differentiated bimolecular layer, local variations in potential and polarity might be very considerable.

I am grateful to Drs. R. H. J. Brown, K. E. Machin and J. W. S. Pringle for discussions during the course of this work.

VIRTUAL ABSENCE OF GLUTATHIONE INSTABILITY OF THE ERYTHROCYTES AMONG ARMENIANS IN IRAN

By Dr. J. E. BOWMAN
Department of Pathology, Shiraz Medical Centre, Nemazee Hospital, Shiraz
AND
Dr. D. G. WALKER*
Department of Biochemistry, University of Shiraz, Iran

THE glutathione (GSH) stability test of the erythrocytes developed by Beutler[1] and studies by the University of Chicago group[2] have resulted in the discovery of a genetic erythrocytic defect, namely, an absence or a deficiency of the enzyme glucose-6-phosphate dehydrogenase. This erythrocytic defect is found in some ethnic groups but not in others[3-6]. In general, American and North European Caucasians, Askhenazic Jews, American and Peruvian Highland Indians and Japanese do not have the defect. However, American Negroes, Sephardic Jews, Sardinians, East and West Africans, and some Asians, have the genetic defect to an extent such that tests for deficiency of this enzyme have become valuable anthropological tools. Recently we reported that approximately 8 per cent of Moslems in Iran are sensitive by the GSH stability test[7]. Several tribal groups studied thus far have also shown incidences of the

---

* Present address: Department of Biochemistry, University of Birmingham, Edgbaston, Birmingham 15.

defect similar to the Moslem group and even higher, for example, an incidence of 15 per cent in the Mamassani tribal group[8].

This report is concerned with an examination of 163 Armenians, 153 of whom reside in New Julfa near Isfahan. The subjects comprised 152 males and 11 females. Of this group, only one male was found to be sensitive by the GSH stability test of the erythrocytes, making this population the first thus far studied to be virtually negative for the defect in Iran. Unfortunately the one 'sensitive' person could not be traced for requestioning as to possible admixture with another ethnic group. Blood samples were taken from apparently healthy subjects only, but this does not exclude the possibility that this male could have had congenital non-spherocytic hæmolytic anæmia, which is another condition where erythrocytes from such persons also show the enzymic defect[5]. The virtual absence of the genetic defect in Armenians is of greater importance than the finding of the defect in this ethnic group.

According to Montague[9], Armenians are a composite of an Atlanto–Mediterran component and a greater Irano–Afghan element with some Nordic and Alpine elements. From studies of *ABO* blood groups published thus far[10], the Alpine component is very strong for there is an extremely high frequency of the *A* gene. This was confirmed in our *ABO* studies on this population (gene frequency : *p*, 0·3894 ; *q*, 0·1084; *r*, 0·5022, D/σ, + 0·3). The *cde* gene frequency was 0·3941, which is also European. These studies of blood groups of Armenians are distinctly different from those of Boué and Boué[11] on other populations in Iran and our own unpublished observations.

The Armenians once occupied a large part of the area which was the seat of the Hittite Empire (present-day Turkey) and they are believed to be descendants of these people. It is of interest to note that authorities are divided as to whether the Hittites, with their Indo-European language, came originally to Anatolia about 2,000 B.C. from the north-west from northern Europe or from the north-east across the Caucasus Mountains[12]. Be that as it may, there can be no doubt that there is a distinct northern European influence in Armenians from the present study and those of other workers. This northern European influence is strong, despite the fact that the Armenians throughout their long history and by virtue of being situated along the trade route between East and West have been in association with diverse ethnic groups which have and probably did have the gene for glucose-6-phosphate dehydrogenase deficiency, such as Phœnicians, Africans, Jews, Greeks and Iranians.

The Armenians in New Julfa were brought to Iran as Christian captives in 1604 and 1605 by Shah Abbas the Great from Julfa in what is now Soviet Armenia[13,14]. Rather than being treated as slaves, they were encouraged to create a prosperous trade centre between East and West in the area of Isfahan. The original number was about 25,000 ; the present population is about 6,000[14]. The decrease in size is due to movement of many to other parts of Iran and to other countries, mainly India. While religious intolerance has not been permitted in Iran for many centuries, the Armenians were not encouraged to intermarry with the surrounding population. According to Dr. Caro Minasian, an Armenian physician and scholar, Armenians who have intermarried live outside of the area of New Julfa. This fact is supported by our finding of a virtual absence of the erythrocytic defect and by the blood group data. This population is thus an excellent example of what has been termed 'religious isolates' by Montague[9]. Since the original group brought to Iran was fairly large, it is unlikely that the genetic defect was present in the population and then lost during the last 355 years as a result of 'genetic drift'.

Of further interest is the fact that both the area in which the Armenians now live and their original homeland have been, until recent years, regions of high endemicity so far as falciparum malaria is concerned[15]. Several reports have noted that the gene for glucose-6-phosphate dehydrogenase deficiency coincides with the incidence of falciparum malaria in many parts of the world and have suggested that this harmful gene might possibly be maintained as a result of balanced polymorphism with respect to this disease[6,16]. The Armenians in the Isfahan region represent one group which has resided in a malarious area for centuries without the appearance of this protective effect.

During the course of the survey, the subjects and others in the area were questioned about the ingestion of fava (broad) beans, which are agents having an adverse effect on carriers of the genetic defect[8]. Although practically all of them ate fava beans regularly in the spring of the year, neither the subjects nor the physicians in the New Julfa area were aware of any difficulty as a result of eating this food. This is unlike our experience with the Moslem and Jewish groups in Iran. Most of these people are familiar with the possible harmful effect of the *Vicia faba* bean.

It appears to be very important that other workers who have access to Armenians should make studies comparable with ours. The findings of either a high incidence of the genetic defect or a virtual absence such as we have found in Armenians in New Julfa would be of great interest to anthropologists and geneticists.

We wish to express our appreciation to Dr. Caro Minasian for making this survey possible and for his clarification of many points regarding the history of the Armenians. We thank Messrs. Galoost Galestian, Wayburn D. Davies and Parviz Haghighee for assistance on the survey, Misses Annerose Oemisch and Iran Haffarian for technical assistance in the laboratory and Dr. Garegin Saroukhanian for his translation of several Russian sources on malaria in Soviet Armenia.

OBITUARIES

Prof. H. W. Turnbull, F.R.S.

By the death of Prof. Herbert Westren Turnbull at Grasmere on May 4, Britain has lost a distinguished mathematician of the older school, while many mathematicians in England and Scotland have lost a personal friend.

Herbert Turnbull, a son of W. Peveril Turnbull, H.M. inspector of schools, was born in Wolverhampton in 1885. From Sheffield Grammar School he went as a scholar to Trinity College, Cambridge, being Second Wrangler in 1907, first in the first division of Mathematical Tripos II in 1908, and Smith's Prizeman in 1909. After a varied experience of lecturing at Cambridge, Liverpool and Hong Kong, he seemed for a few years to be likely to follow his father's career, teaching as he did at Repton for three years and becoming an H.M. inspector of schools. This pattern was quite altered in 1921 by his appointment to the chair of mathematics in the United College, University of St. Andrews.

The result was to associate his name permanently, and especially to Scottish mathematicians, with St. Andrews. He wrote there the great majority of his sixty or more published papers, and founded a school of algebra and geometry of the older type which, though younger mathematicians have moved to the more modern abstract disciplines, had value in its day. Turnbull was inspired immediately by J. H. Grace and Alfred Young, his associates and seniors by slightly more than a decade at Cambridge, and through them by the Continental masters Clebsch, Gordan and Capelli, with Cayley and Sylvester beyond again. The realm most congenial to him was that of the invariants and covariants of algebraic forms, as investigated by the Clebsch–Aronhold symbolic calculus, of which he became the last and in some ways perhaps the greatest master; but he was constantly aware of the applications to projective geometry. Also, when in 1927 Alfred Young began his new attack on invariants with the Frobenius–Schur group algebra of the symmetric group, Turnbull was fully alive to the new range thus opened, and some of his work consists of a reconciliation of the symbolic with the group-algebraic approach. His name will also be associated with memoirs and text-books on matrices and determinants.

An interest in the history of mathematics first found utterance in a small book, *The Great Mathematicians* (1929); but the discovery of hitherto unknown documents relating to the work of the Scottish mathematician, James Gregory (1638–75), produced his first historical work on a larger scale, the *James Gregory Tercentenary Memorial Volume*. Felicitously, this was ready in time for the James Gregory tercentenary celebrations which, somewhat resembling the Napier tercentenary celebrations of 1914, took the form of an international congress of the Edinburgh Mathematical Society—the University of St. Andrews and the Royal Society of Edinburgh being sponsors. This occasion, too soon overshadowed by rumours of war, will be remembered by many as the special one in which Turnbull, in the prime of life and ably seconded by his wife, showed himself as the host of hosts and moreover as an excellent musician, for he was a pianist of almost professional standard. To Scottish mathematicians these qualities were well known, in the annual June meeting of the Edinburgh Mathematical Society at St. Andrews and its four yearly colloquia held there.

Retiring in 1950, Turnbull as emeritus professor devoted himself to his second and major historical work, the editing of the correspondence of Isaac Newton. He lived to see the first volume, handsome and impressive, appear in 1959, and to know that the second was well under way.

His character was founded on the simplest faith, absolute sincerity and the desire to serve. His many friends, in their sympathy extended to his wife and their son Derwent, will remember the man first, and then the mathematician. A. C. Aitken

Prof. C. G. Jung

Carl Gustav Jung, who died on June 6, was born on July 26, 1875, at Kesswyl, in Switzerland. His father was a clergyman and he was brought up in his parsonage in the country. He attended school at Basle and was educated in medicine in that city, where he graduated.

In 1900 he became assistant in the State Mental Hospital and in the psychiatric clinic of the University of Zurich, later becoming senior staff physician there until 1909.

In 1902 he spent six months in Paris attending P. Janet's lectures and worked in Zurich with E. Bleuler. He first met Freud in 1906.

When Freud put forward his ideas and discoveries he had been greeted with scorn and derision until Bleuler made it known that his views were regarded sympathetically by the Zurich school. The interest of the Swiss certainly helped to direct the scientific world towards psychoanalysis, and Freud acknowledged his gratitude, stating, "The Zurich doctors made, as it were, the nucleus of the little band which was fighting for the recognition of psychoanalysis. Only in Zurich was there a possible opportunity to learn the new art and to apply it in practice".

Freud at this time wished to take a less prominent place in the Psychoanalytical Society and diplomatically transferred his presidency to Jung.

Jung must have been an impressive young man in those days, and Wittels described him in his well-known depiction as "Tall and upright of figure, like a young Siegfried". When I first saw him some thirty years ago he was middle-aged, but still well built, with a rather burly figure, a jovial red face, short clipped hair, and gold-rimmed glasses. He was a good lecturer and able to impress an audience with his profundity. With those who sought his views he had a kindly, serious manner and he was certainly 'a good mixer'.

The first important investigation of note which he made was his careful study of association. His research followed on the experimental work started by Galton in 1879 and Wundt a year later. This was 'controlled association' or the timing of words associated with those already provided. This led to the development of the conception of 'the complex' or group of ideas, emotionally charged, capable of influencing conduct and thought. Following on his work on association Jung did some valuable research on schizophrenia, published under the title of *The Psychology of Dementia Precox* (1909).

He remained president of the International Psychological Society until 1913, when he published his book on *The Psychology of the Unconscious*, which was a study of mythology. This showed such a deviation from psychoanalysis that he resigned. The Zurich and Vienna schools then drifted apart.

After this Jung advanced his well-known theory of psychological types. This was a development of philosophical views known from the earliest times and used by William James, who thought men were divisible into tough and tender, by Schiller who thought them idealists and realists and so on. However, the two main types Jung described were extroversion and introversion, but complicated by the addition of sub-classes of thinking and feeling, so that there were eight in all. Extroversion and introversion have become household words.

Jung moved further and further from clinical psychiatry and more and more towards an interest in mythology. His later works were, *The Secret of the Golden Flower* (1930), *Modern Man in Search of His Soul* (1933), *Psychology of Religion* (1939), and *The Integration of the Personality* (1940), etc.

Although Jung's investigation of myths is regarded with suspicion by many psychiatrists, since it is impossible to prove the correctness of an interpretation, and the application of myths to the understanding of clinical illness is of uncertain value, most accept that Jung's earlier work on association, complexes, schizophrenia and psychological types is of immense value.

He was a tireless writer and lecturer. He visited most countries at the invitation of learned societies and studied myths all over the world. The last of the triumvirate formed by him with Freud and Adler, his death represents the passing of a great epoch of psychiatry. CLIFFORD ALLEN

NEWS and VIEWS

Electrical Engineering at Glasgow : Prof. J. Lamb

DR. JOHN LAMB has been appointed to the James Watt chair of electrical engineering in the University of Glasgow, in succession to the late Prof. B. Hague. For the past five years Dr. Lamb has been a reader in electrical engineering in the Imperial College of Science and Technology, London. He is well known for his many contributions to knowledge in the fields of ultrasonics and the physics of materials. Dr. Lamb is thirty-nine years of age. He graduated in electrical engineering in the University of Manchester in 1943, and was awarded the degree of Ph.D. in 1946 and the degree of D.Sc. in 1957. In 1947 he joined the staff of the Imperial College. For the past three years, in addition to his readership, he has held the appointment of assistant director in his Department, involving administrative responsibilities that will no doubt have given him experience that will be of value in taking charge of a department. It may be expected that the appointment of Dr. Lamb will ensure that electrical engineering in Glasgow will be developed on modern lines and with a keen appreciation of the part that advances in basic physics must play in the future of electrical engineering.

Beilby Medal and Prize, 1961

THE administrators of the Sir George Beilby Memorial Fund, representing the Royal Institute of Chemistry, the Society of Chemical Industry and the Institute of Metals, have decided to make awards from the Fund in 1961—each consisting of the newly instituted gold medal with a prize of 100 guineas—to Dr. Constantin Edeleanu and Prof. Jack Nutting.

Dr. C. Edeleanu

DR. C. EDELEANU was born in Rumania, and wen to Britain in 1937. He was a pupil at the Morrison Academy, Crieff, and then went up to Cambridge in 1941. In 1946 he joined Dr. U. R. Evans, working on the stress corrosion of light alloys. In the course of that work he became interested in pitting reactions and developed the autocatalytic mechanism for pitting first proposed by Dr. Hoar. A somewhat surprising conclusion of the work was that the true rate of corrosion during the pitting of aluminium in a given solution was a constant. Direct experimental proof of this was, however, only obtained some ten years later. In 1950 he joined the Brown Firth Research Laboratories, where he was in charge of a section dealing with long-term alloy development. Stress corrosion, especially in high-pressure water systems and nuclear-reactor cooling systems, was of particular interest, and the work demonstrated that failures in such systems were, as a rule, associated with concentration effects arising either during heat transfer or in heating and cooling cycles. In 1956 he joined the Tube Investments Research Laboratory at Hinxton, to form a corrosion group. At first the work consisted mainly of studying the factors that control corrosion in some fused-salt systems of interest to the nuclear-engineering industry. One of the main results was to show that such systems could be treated in a somewhat analogous way to aqueous systems but that there were important differences. More recently, Dr. Edeleanu has returned to stress corrosion and, in conjunction with Dr. A. J. Forty, has attempted to interpret this type of failure in a more physical manner. This led naturally to the question of the part played by dislocations and other structural features in corrosion. With G. A. Bassett a start was made in this field, techniques such as transmission electron microscopy having played a useful part.

Prof. J. Nutting

PROF. J. NUTTING was educated at Mirfield Grammar School, Yorkshire, and the University of Leeds. He was then appointed research assistant to the late Prof. Preece at Leeds and was awarded the degree of Ph.D. in 1948 for a dissertation on the overheating and burning of steel. Afterwards he was employed by the British Iron and Steel Research Association and was seconded to the Cavendish Laboratory, Cambridge, where he worked with Dr. V. E. Cosslett and Prof. E. Orowan, developing techniques for the examination of metals with the electron microscope. In 1949 he was appointed demonstrator and in 1954 lecturer in the Department of Metallurgy, University of Cambridge—an appointment he held until 1960, when he returned to the University of Leeds as professor of metallurgy in the Houldsworth School of Applied Science. During his work at the Cavendish Laboratory he became convinced that the electron microscope could be more widely applied to problems in metallography. On transferring to the Metallography Department in Cambridge he had the opportunity of testing his convictions, and together with a group of research students a wide variety of metallographic problems was investigated.

Paul Instrument Fund Committee Grants

AWARDS of grants by the Paul Instrument Fund Committee have been made as follows: £1,550 to Dr. E. T. Hall, director of the Research Laboratory for Archæology and the History of Art, Oxford, for the design and manufacture of a recording instrument combining a drum recorder and servo transmitters with a spectrometer to give a direct reading of wavelength; £3,900 to Dr. P. B. Hirsch, lecturer in physics, University of Cambridge, for the construction of an electron optical instrument which will measure the energy distribution of the electron beam passing through small areas (diameter less than 1μ) in the crystal specimen which can be observed and selected on the electron microscope image; £3,000, in supplement of a previous grant, to Dr. H. Motz, Donald Pollock reader in engineering sciences, University of Oxford, for the construction of a linear accelerator working at 1·6 cm. (*J*-band); £2,284 to Mr. B. M. Turner, who is working in the Department of Zoology and Comparative Anatomy, Oxford, for the further development of micro-scale chromatography and electrophoresis techniques.

The Paul Instrument Fund Committee, composed of representatives of the Royal Society, the Institute of Physics and the Physical Society and the Institution of Electrical Engineers, was set up in 1945 "to receive applications from British subjects who are research workers in Great Britain for grants for the design, construction and maintenance of novel, unusual or much improved types of physical instruments and apparatus for investigations in pure or applied physical science".

U.S. Scientists in Universities and Colleges : 1958

A PRELIMINARY report on scientists and engineers engaged in research and development in colleges and universities in the United States for 1958, issued by the National Science Foundation (*Reviews of Data on Research and Development*, No. 27; April 1961), gives the number of those engaged as 69,919 in 377 colleges and universities, or 44 per cent of all scientists and engineers employed at colleges and universities in 1958, and the expenditure as 736 million dollars, compared with 410 million dollars in 1954. Of these, 47 per cent were employed in the biological sciences, 26 per cent in the physical sciences, 17 per cent in engineering sciences and 10 per cent in the social sciences. Operating expenditure for separating budget research and development at the universities and colleges accounted for 45 per cent of the total expenditure on research and development, agricultural experiment stations for 16 per cent, and Federal Contract Research Centres for 39 per cent. Sixteen institutions employing 1,000 or more employed 31,260 of this total of scientists and engineers, and twenty institutions with 500–999 another 14,026, while 206 institutions employed fewer than 25 scientists and engineers. While the total faculty engaged in research and development only rose by 3 per cent between 1954 and 1958, the number of faculty engaged full-time in research and development increased by 49 per cent.

Production of Gas from Coal in Britain

IN a written answer in the House of Commons on June 23, the Minister of Power, Mr. R. Wood, said that he had accepted the advice of the Wilson Committee that town gas offered the greatest scope for expansion in making gas, oil and chemicals from coal, but that new plants would be required to make gas more cheaply. He had therefore decided, in agreement with the Gas Council and the National Coal Board, to accept the recommendations that the development of high-pressure slagging gasifiers should be pursued; that the Gas Council should be responsible for further work on the standard Lurgi gasifier using British coals, on the Otto–Rummel gasifier and on any further gasifiers suitable for town gas, as well as for development on slagging gasifiers; and that the National Coal Board should be responsible for work on producer gas plants. He also accepted the Committee's view that the prospects of making oil from coal economically in Britain are so remote that no further technological work on the development of this process should be undertaken at present. The Department of Scientific and Industrial Research had accordingly terminated its development work on this process, but was continuing basic investigations on catalysis and keeping in touch with developments in making oil from coal. The Minister said that his Department, which had been carrying out research and development on the slagging gasification of coal as a raw material for oil synthesis, would continue this work until March 31, 1962, when the Gas Council would be responsible for all work in this field. The Gas Council and the National Coal Board were making a joint economic study of the possibilities of the Lurgi process which might later be extended to include slagging gasification. This study would define the scope for further developments of the process and provide a basis for further co-operation between the Gas Council and the Board in the total gasification of coal.

Research on West Indian Volcanoes

GEOLOGICAL work is in progress on volcanoes in the West Indies, by the Department of Geology and Mineralogy, University of Oxford, in co-operation with the Seismic Research Unit of the University College of the West Indies. In view of the large amount of geophysical data available on this region, it is desirable that a detailed petrological study of the volcanic rocks of the British Leeward and Windward Islands be undertaken. A succession of Oxford graduate students will work on specific problems during the next five years, under the supervision of Prof. L. R. Wager and Dr. G. M. Brown (University of Oxford) and with assistance in the field by Dr. G. R. Robson (Seismic Research Unit) and Dr. P. H. A. Martin-Kaye (Government Geologist, Windward Islands). Their work will include mapping of the structure of the volcanoes and the recognition and classification of the various phases of recent volcanic activity. Petrological and mineralogical work on the rocks and minerals will, in conjunction with the field work, lead to a better understanding of the origin of the rocks and of some of the causes underlying the development of volcanic episodes in the region.

Work has begun with studies by Prof. Wager on the petrology and mineralogy of plutonic blocks ejected by the Soufriere Volcano, St. Vincent (1959 visit), and by P. E. Baker on the strato-volcano, Mt. Misery, on St. Kitts (1961 visit). Other students will begin work shortly on St. Lucia and Dominica, which are characterized by having centres of activity concentrated in almost circular caldera-type depressions, in which tholoids and ash deposits predominate and in which fumarole activity and earth tremors have persisted in recent years.

Education by Television

As a tool for instruction, television is accepted and well established in the United States. Television made its first appearance in education as long ago as 1932 at Iowa State University, but it was not until 1953 that it was first used for normal instruction. By 1960, half a million school-children and 100,000 college students were receiving regular instruction by television. This situation is in marked contrast with that prevailing in Great Britain. In a pamphlet entitled *Educational Television: a Survey and a Plan*, which has been published privately, John Wellens shows that in Britain educational television is practically synonymous with the schools television service run by both the B.B.C. and the independent network (Pp. 44+8 plates. Guilsborough, near Northampton: John Wellens (ITT), Ltd., The Sun House, 1961. 5*s*.). The only exception consists of a handful of colleges and universities which have their own closed-circuit installations for giving instruction in special departments, such as medicine, dentistry and engineering. These installations are few and have only recently been introduced; in many cases they have not yet developed beyond the pilot stage. In some cases the installations have been put in, below economic cost, to promote the acceptance of television as a teaching tool. Two Middlesex schools have been linked by micro-wave equipment for the teaching of chemistry, but, none the less, Britain is now at the stage reached by the Americans approximately ten years ago. Within the past year British educationists have become aware of the activity in this field in the United States and, in his booklet, Wellens describes the present position in the United States and makes a practical evaluation for Britain.

Research Defence Society

THE Research Defence Society has published another of its pamphlets to make known the facts about experimental research involving the use of animals, and the conditions and regulations under which animal experiments are conducted in the United Kingdom. *Animal Experiments in the Control of Animal Diseases* is set out on the lines of previous pamphlets, that is, by posing a series of questions which the general public could rightly ask and by providing answers which are as objective and free from bias as humanly possible (Pp. 6. London: Research Defence Society, 1961. 6*d*.). In this new pamphlet the questions posed include: "Why are the treatment and prevention of animal disease important enough to warrant animal experiments ? Why is animal experiment necessary to help in combating animal disease ? Can you give examples of new agents for control of animal disease which would not have been developed without animal experiment ? Can you explain the paradox that animal experiments involving suffering are used to prevent suffering in other animals ? Why are animal tests necessary in the development of new drugs ? How do animal experiments help in the control of animal disease ? Why are animal experiments necessary in the safety testing of vaccines for use in animals ?"

The Museums Journal

EARLIER this year it was decided to discontinue the monthly *Museums Journal* and publish instead a monthly *Bulletin* and a quarterly *Journal*. The first issue of the latter publication (No. 1; June 1961) was awaited with interest. The decision of the Council is fully justified, and curators are certainly not disappointed, for the new format even exceeds expectations. Mr. R. L. S. Bruce-Mitford describes the Book of Kells exhibition, stressing the technical presentation; Mr. Ronald Alley, in a comprehensive analysis, proves the almost total failure of British art galleries to acquire modern pictures and sculptures of foreign schools; and Mr. Stanley Rubenstein deals with the complicated problems of copyright. On the purely technical side, Mr. R. M. Organ gives a new treatment for 'bronze disease', and Mr. A. M. Tynan describes the uses of 'Styrocell'. Mr. Hugh Wakefield details the practical nature of the purchase grants made by the Victoria and Albert Museum. The issue also includes the annual report of the Museums Association for 1960–61, and a well-balanced *Journal* concludes with notes on the contributors and research work in progress.

The Victorian American

IN 1960 the family of the late Harry T. Peters presented the 'American on Stone' collection of lithographs to the Smithsonian Institution (Publication 4466: *The Victorian American*. By Antony N. B. Garvan and Peter C. Welsh. Lithographs from the Harry T. Peters 'American on Stone' Collection. Pp. 30. Washington, D.C.: Smithsonian Institution). The collection touches on every phase of American life in the nineteenth century. Part of this interesting material is now on tour as a travelling exhibition, and the 100 lithographs listed in a well-prepared catalogue include those illustrating technical progress, suburban novelty, rural nostalgia, the family and the genteel female, sports, fashion, the sea, politics, warfare and humour.

Medical Research in East Africa

A NEW treatment for tuberculosis and investigations into the causes of eye diseases in Africans are among the many items referred to in the report of the East African Council for Medical Research for 1959–60 (Pp. ii+15. Nairobi: Government Printer, 1960. 2*s*.). In tuberculosis, the important finding has been that thiacetazone (thiosemicarbazone), TB1, is as efficacious in combination with isonicotinic acid hydrazide (INAH) in therapy and in preventing drug resistance as is *para*-aminosalicylic acid (PAS). TB1 is cheap and palatable; PAS is expensive and patients dislike it. They are apt, therefore, to take INAH alone and thus acquire resistance to infections. A high (about 10 per cent) and increasing incidence of initial drug-resistance has been revealed in new and presumably untreated cases. The investigations now in progress are to determine the optimum dosage. Surveys have been carried out to determine the most common eye conditions in different African communities. A higher incidence of non-leprous eye disease was found in lepers in the Central Province than in Lake Province, and this is probably due to trachoma and pterygium being common in the former area. In the foothills of the Ruwenzori Mountains of West Uganda, onchocerciasis is common; it was found that this filarial infection was the most important cause of blindness. Some investigations into the ability of the African to accommodate were made. Although during early life accommodation is poor, it does not deteriorate so rapidly in late middle-life as it does in Europeans. Colour vision was also tested, and it was confirmed that the incidence of red-green and other forms of colour-blindness is lower in Africans than in Europeans.

Diabetes Mellitus in Africans in Rhodesia

A SURVEY carried out recently on Salisbury Africans by Dr. M. Gelfand and W. R. Carr indicates that diabetes is less prevalent than in most other parts of the world, particularly in comparison with areas where more processed and highly refined foods are purchased (*Central African Journal of Medicine*, 7, No. 2; February 1961). The diets with traditionally high carbohydrate, low fat and low animal protein contents are probably the main factor involved in keeping the disease at a low level. There are increasingly large numbers of Africans whose diet is changing tremendously during short periods of time towards higher fat, refined sugar and animal protein consumption, but, as yet, they are insufficient in numbers to indicate whether this will have an effect on the incidence of diabetes and, *inter alia*, coronary thrombosis. The socio-economic background shows that most of the diabetic patients come from groups who work in the European economy, and whose diet has been altered to include more foods containing, in particular, refined sugar and fats. The clinical types encountered in Rhodesia correspond very closely with the European pattern. No variants such as *J* or *K* types are found. The African diabetics may require more insulin than the European for stabilization, but this may be due to lack of understanding of the need to follow a strict dietary routine. The level of blood-sugar was found to be higher than in a European group and this may be the reason for the difference. Although the insulin requirements of the African appeared to be high, hypoglycæmia coma developed if the requirements were exceeded. The symptoms of diabetes appear to be the same for the African and European, the main features being thirst, polyuria, weakness, loss in weight and pruritus vulvæ; but there were certain differences, such as the infrequency of pulmonary tuberculosis, gangrene and intercapillary glomerulosclerosis.

Ecological Aspects of Irrigation in Ancient Mesopotamia

A PAPER by Hans Helbaek, "Ecological Aspects of Irrigation in Ancient Mesopotamia" (*Iraq*, 22, 186; Spring and Autumn, 1960. Published by the British School of Archæology in Iraq), develops the argument that man first harvested his grains (barley and linseed, in particular) where the wild plants grew on hills in the Near East, and on soils fed by rain. Here he supposes the genetic constitution of the crop plants remained fairly constant. But some 7,000 years ago man sowed and grew his wild barley in the plain of Mesopotamia in rich land naturally irrigated by flooding (and later artificially irrigated by canals). Here presently the wild 2-row barley gave rise to a 6-row barley by a moderate genetic change causing the two lateral abortive spikelets to become fertile. Helbaek claims to have produced such a barley as a mutant from a 2-row wild barley by X-ray irradiation. Such 6-row barley was welcomed by early man, and spread to Egypt and elsewhere. Meanwhile, continued irrigation in Mesopotamia led to salt accumulation in the soil and the disappearance of crops, first of the sensitive Emmer wheat, then linseed, and finally of barley, and with that of man. Helbaek gives evidence also that while early man's *Linum* seeds (whether flax or linseed) remained constant in size for some thousand years by areas fed by rainfall, the size of seed steadily increased in areas with irrigation. Readers interested in the botanical history of crop plants and of the early growth of civilization made possible by crops should read and assess this short paper themselves.

Taxonomy of the Earthworm in India

EARTHWORMS, apparently sent simultaneously to the British Museum (Natural History) and to the American Museum of Natural History for identification, have directed attention once more to the deplorable state of the taxonomy in a genus that may be dominant in a considerable portion of the Indian Peninsula. Each of the species left in that genus by a revision by G. E. Gates in 1939, based on an over-all somatic rather than genital anatomy, has remained indefinable hitherto. Material now studied by Gates, at the University of Maine, has enabled recognition not only of two further characters for generic definition but also has permitted, for the first time, fairly satisfactory characterization of a species based on data such as variation in sexual individuals secured in lots of some size from several localities (*Ann. Mag. Nat. Hist.*, 3, No. 35; November 1960). Previously unpublished information included in his account was obtained from 90 specimens collected for him at three localities in the Jubbulpore region during the Second World War.

Geology of the Country around Monmouth and Chepstow

THE Geological Survey of Great Britain has now published a composite Memoir covering the geology of the country around Monmouth and Chepstow (Department of Scientific and Industrial Research Memoirs of the Geological Survey of Great Britain—England and Wales. By Dr. F. B. A. Welch and Dr. F. M. Trotter. With contributions by T. R. M. Lawrie, J. D. D. Smith and R. W. Elliot. Pp. viii+164+2 plates. London: H.M.S.O., 1961. 22*s*. 6*d*. net). Previously, this area was dealt with in separate Memoirs and Survey sheets, but the present Memoir is an explanation of New Series Geological Sheets 233 (Monmouth) and 250 (Chepstow)—an area occupying a total of 432 square miles, of which some 46 square miles are covered by the Severn Estuary; a little more than half lies within Monmouthshire, part in Herefordshire and the remainder in Gloucestershire. The Memoir details the geological sequence and history of the area, which extends from the Ludlow Series of the Silurian rocks through Old Red Sandstone, Carboniferous, Triassic, Jurassic to recent superficial formations. A general account of the geological structure of the region is included, also an analysis of those earth movements which have affected the area. Each geological epoch represented is treated individually, and bibliographies of the literature are provided. A short chapter deals with the igneous rocks of the area, and another concerns itself with the economic deposits. Two appendixes provide records of recent important bore-holes, and also a list of Geological Survey photographs of the area.

The Art of Interviewing

The British Association for Commercial and Industrial Education has produced a pamphlet which should find readers well outside the range of those for whom it was intended. Written by John S. Gough, of I.C.I., Ltd., the pamphlet *Interviewing in Twenty-six Steps* describes the approach to an interview designed to select a candidate for a job, the method of conducting it, the dangers and diversions to be avoided and the way the interview should be used in summing-up the candidate. The pamphlet is forthright, practical and has clearly been written by one who has tried out his twenty-six steps on many occasions before summarizing them in this form. Gough makes it clear that no skilled interviewer can guarantee success in selection; the more he practises, the less mistakes he should make. This pamphlet will help him to reduce his number of failures. Copies may be obtained from the British Association for Commercial and Industrial Education, 26*a* Buckingham Palace Road, London, S.W.1; price 3*s*. 6*d*.

Applications of Solar Energy

In *Solar Energy Technology: 1954–1959* (Library Association. Special Subject List No. 34. Pp. 32. London: Library Association, 1961. 3*s*. 6*d*.), T. Brimelow attempts to list all the significant literature on the subject published in Europe and the United States with the exception of items published in the popular and political periodicals of the U.S.S.R. The 329 items are arranged in sections which include: aero/space applications; air-conditioning; automotive engineering; biological science; electrical conversion; furnaces; heating; radio; refrigeration; water heating and water treatment. There are an author index and also a subject index, and a brief introduction by Dr. H. Heywood notes the salient features in present applications of solar energy.

Scientific Research in British Universities, 1960–61

Scientific Research in British Universities, 1960–61, issued by the Department of Scientific and Industrial Research, is an indispensable handbook for all those who endeavour to keep track of scientists in the United Kingdom and their fields of research (Pp. xiii + 513. London: H.M.S.O., 1961. 32*s*. 6*d*. net). The handbook describes the nature of research projects in progress, and indicates the scope of research carried out by various scientific departments and individual teams of investigators. Entries are made in alphabetical order of university, and subdivided into faculty and subject. Simple numerical headings of universities and subject allow ease of reference. Three indexes are provided, satisfying any search by name, subject heading or actual research.

Lady Tata Memorial Trust: Awards for 1961–62

The Trustees of the Lady Tata Memorial Trust, on the recommendation of the (European) Scientific Advisory Committee, have made the following awards for research on leukæmia and allied diseases in the academic year beginning October 1: *Grants for research expenses*, Dr. J. L. Amiel, Cancer and Radiopathology Research Centre, Paris; Dr. B. M. Braganca, Indian Cancer Research Centre, Bombay; Dr. G. W. Griffith, County Health Department, Anglesey; Dr. B. Lagerlof, Karolinska Institute, Stockholm; Dr. H. J. Woodliff, New Pathology Laboratory, Radcliffe Infirmary, Oxford. *Scholarship*, Dr. L. Chieco-Bianchi, Institute of Pathological Anatomy, Bari.

Awards in Radiological Research and Nuclear Medicine: James Picker Foundation

On behalf of the James Picker Foundation, the National Academy of Sciences—National Research Council is accepting applications for fellowships and grants in the field of radiology and nuclear medicine for the year 1962–63. Awards are made in four categories: (1) *Advanced Fellowships in Academic Radiology*. Completion of clinical training in radiology ordinarily will be a prerequisite, and the candidate must be prepared to devote a minimum of two years to course work in the basic sciences and to the application of the techniques and methods of these basic disciplines to radiological research. (2) *Post-doctoral Research Fellowships*, open to recent graduates who desire investigative experience and training in radiology or nuclear medicine. Applicants must hold the M.D., Ph.D. or Sc.D. degree or the equivalent. Awards are for a period of one year. (3) *Grants for Scholars*, to assist medical schools in supporting and developing junior staff members in radiology. Initial grants are made for two years. (4) *Grants-in-Aid of Research* are designed to encourage investigations in radiology and nuclear medicine offering promise of improvement in methods of diagnosis or treatment of disease. These grants may be made for two years. Applications for the fiscal year 1962–63 should be submitted by October 1, 1961, to the Committee on Radiology, National Academy of Sciences—National Research Council, 2101 Constitution Avenue, N.W., Washington 25, D.C.

The Institute of Physics and the Physical Society

At the first annual general meeting of the amalgamated Institute of Physics and the Physical Society, held in London on July 4, the following were elected to office: *President*, Sir John Cockcroft; *Vice-Presidents*, Dr. V. E. Cosslett, Prof. R. W. Ditchburn, Dr. W. H. Taylor and Dr. J. Topping; *Honorary Treasurer*, Dr. J. Taylor; *Honorary Secretary*, Dr. C. G. Wynne. Eight ordinary members of Council were also elected. This, the first elected Council of the amalgamated body, is very nearly the same as the 'caretaker' Council which has been in office since the amalgamation of the Institute and Society on July 5, 1960.

University News: Leeds

The Foundation for Management Education has arranged for grants totalling £16,600 a year for seven years to be made available to the University of Leeds. This will make possible the strengthening of the present teaching in management studies for students mainly in the Faculty of Technology; and the expansion of the work with residential and non-residential courses for upper and middle managers, and the establishment of a one-year postgraduate diploma course in industrial management. It will also enable the University to gain the assistance of a number of visiting lecturers, and to set up a number of scholarships and fellowships for research in the field of management and business studies.

The following appointments to lectureships have been announced: Dr. A. Chadwick (zoology); Dr. B. L. Shaw (inorganic and structural chemistry). Mr. F. P. G. Whitaker, at present lecturer in industrial management, has been appointed director of management studies in the Department of Economics and Commerce.

London

Dr. J. S. Webb, reader in applied geochemistry at the Imperial College of Science and Technology, has been appointed to the University chair of applied geochemistry tenable at that College. Dr. F. G. A. Stone, assistant professor at Harvard University, has been appointed to the University readership in inorganic chemistry tenable at Queen Mary College from July 1, 1962. The title of reader in biology in the University of London has been conferred on Dr. Agnes M. Hughes in respect of her post at the Royal Free Hospital School of Medicine.

Prof. J. N. P. Davies, professor of pathology at Makerere College, has been appointed to the University readership in morbid anatomy tenable at the Postgraduate Medical School of London. Mr. H. D. Ritchie, assistant director of the Surgical Unit at the London Hospital, has been appointed to the University readership in surgery tenable at the London Hospital Medical School.

Titles of reader in the University have been conferred on: Mr. R. W. Fearnhead (dental anatomy), in respect of his post at the London Hospital Medical College; Dr. T. G. Bonner (organic chemistry), in respect of his post at Royal Holloway College.

North Staffordshire

The University College of North Staffordshire, Keele, is to become Keele University in 1962. H.R.H. Princess Margaret, who is at present president of the College, has been proposed as the first chancellor of the new University.

The following appointments have been announced: H. Liebeck, to a lectureship in mathematics; Dr. M. Asgar Ali, to an Imperial Chemical Industries research fellowship; M. J. A. Smith, to be Mullard Research Fellow in physics; Dr. W. P. McCann, to be Leverhulme research officer.

Oxford

The first award of the J. H. Burn fellowship, at the Department of Pharmacology, for 1961–62 has been made to Mr. H. P. Rang.

Sheffield

The following have been appointed to readerships: Dr. L. Mirsky (pure mathematics); Dr. V. R. Pickles (physiology); Dr. F. A. Benson (electronics). G. Lederer has been appointed as a lecturer in pure mathematics. Dr. P. B. N. Neal is to be senior Research Fellow in mechanical engineering, and Mr. A. B. Hedley has been appointed to the Central Electricity Authority research fellowship in fuel technology.

Announcements

The David Anderson Berry Prize for 1961 of the Royal Society of Edinburgh has been awarded to: (*a*) Drs. H. B. Hewitt and C. W. Wilson (Westminster Hospital School of Medicine, London) for their quantitative estimation of the lethality of radiation on leukæmia cells *in vivo*; and (*b*) Dr. D. H. Sussdorf (research fellow in immunochemistry, Division of Chemistry and Chemical Engineering, California Institute of Technology, Pasadena) for his studies on the re-population of the spleen of X-irradiated rabbits by lymphoid cells from shielded regions.

Dr. J. F. Goodman has been appointed head of the Basic Research Department, Thomas Hedley and Co., Newcastle upon Tyne. Dr. Goodman joined Hedley as a research chemist in 1957, and in 1960 became head of the Physical and Analytical Group in the Basic Research Department.

Dr. Leo P. Vernon has been appointed as director of research of the Charles F. Kettering Laboratory in Yellow Springs, Ohio. Dr. Vernon, who is well known for his work on photosynthesis, is at present on sabbatical leave at the Nobel Institute, Stockholm, from his post as professor of chemistry at Brigham Young University. Dr. Vernon will assume his position at Kettering Laboratory on or about October 1.

The Plant Phenolics Group is holding a meeting on "Wood Extractives" at Royal Holloway College, Englefield Green, Surrey, during September 20–22. Further information can be obtained from the Honorary Secretary, B.L.M.R.A., Milton Park, Egham, Surrey.

"The Fishing Research Vessel" will be the major subject at a forum to be organized by the Food and Agriculture Organization in Tokyo during September 18–30. The meeting will also consider hydrographic survey ships, polar exploration vessels, hospital ships, lighthouse tenders, cable ships and non-magnetic ships. Further information can be obtained from the Food and Agriculture Organization, Rome.

The Systematics Association and the Challenger Society are arranging a symposium on "Speciation in the Sea", to be held at the Plymouth Laboratory of the Marine Biological Association of the United Kingdom, during September 27–29. Further information can be obtained from Norman Tebble, Zoological Secretary, Systematics Association, British Museum (Natural History), Cromwell Road, London, S.W.7.

An Advanced Study Institute on Underwater Acoustics is to be conducted during July 31–August 11 of this year in the Physics Department in the Imperial College of Science and Technology, South Kensington, London, S.W.7. Dr. Vernon M. Albers, chief scientist at the Ordnance Research Laboratory of the Pennsylvania State University, and Dr. R. W. B. Stephens, reader in acoustics at Imperial College, are co-chairmen of the Institute.

The Institute of Physics and the Physical Society is organizing a residential symposium on "Some Aspects of the Physics of Space Research" to be held at the Royal Military College of Science, Shrivenham, Swindon, Wiltshire, during September 20–22. Further information can be obtained from the Administration Assistant, Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

THE BRITISH SPACE DEVELOPMENT CO., LTD.

THE British Space Development Co., Ltd., has been formed in order to bring together a representative cross-section of that part of industry which is interested in the development and exploitation of space for commercial purposes and which believes that the use of space will, in the next two decades, become a major key to the continued prosperity of the United Kingdom and Commonwealth, politically and industrially. It is considered that a successful and economic entry into the new medium of space demands a unified effort on the part of British industry.

Briefly, the initial aims of the Company are as follows:

(*a*) To provide an organization to discuss with the Government and co-operate in any proposals that the Government may make in regard to a United Kingdom and Commonwealth space programme, which is either independent of European participation or which includes European participation.

(*b*) To provide the Government with an indication of the faith that British industry has in the exploitation of space and to show its readiness to play its part and to take its share of the risks as well as its share of the future benefits.

(*c*) To offer the Government an industrial body broadly based to act as an authority or agency to conduct research and development and to implement and operate a space programme and to consider and develop all the possible areas of exploitation of space.

(*d*) To provide those industries concerned with an organization to negotiate with other countries or foreign industrial organizations or consortia any matters concerning the commercial uses of space which are likely to have global implications, that is, communications, broadcasting, television, meteorological forecasting and navigational aids.

(*e*) To provide the greatest economy in the use of the limited number of technical personnel available in the country, particularly in the field of astrophysics and astronautical engineering, and to ensure that duplication of effort, which has been so prevalent in the United States and which has contributed to wasteful use of resources, is avoided in the United Kingdom.

(*f*) To encourage the provision of and to provide directly, in due course, facilities for the training of an adequate number of technical personnel in all those sciences associated with space research and the exploitation of space.

(*g*) To preserve for British industry a place in space and a proper share of the national and international benefits deriving from the development and use of space.

It is possible that the Company may develop into an international company, particularly as no enterprise in the world has as yet been envisaged where such a wide cross-section of industry has come together to pool its resources and effort in order to compete in this demanding, expensive but ultimately most lucrative new technical field with its limitless possibilities.

The British Space Development Co. now being formed will have an initial capital of £20,000. The following Companies will be the initial participants: Associated Electrical Industries, Associated Tele-Vision, British Insulated Callender's Cables, Decca Radar, Hawker Siddeley Aviation, Ltd., Pye, Rank Organization, Rolls-Royce, Plessey, Elliott Automation.

As one of its first major projects, the Technical Committee of the Company is now examining the technical and economic problems of the United Kingdom and Commonwealth satellite communications system which allows for integration with an American system.

Sir Bernard Lovell, professor of radio astronomy in the University of Manchester and director of the Nuffield Radio Astronomy Laboratories, Jodrell Bank, has been appointed scientific adviser to this newly formed Company, though he will retain his present position at Manchester and Jodrell Bank.

THE DEPARTMENT OF SCIENTIFIC AND INDUSTRIAL RESEARCH

THE report of the Council for Scientific and Industrial Research for the year 1960* records gross expenditure for the year ended March 31, 1960, of £12,008,536, compared with £10,059,376 in the previous year, and reduced to £10,342,691 by various receipts from industry and other sources for services rendered. Of the latter, £722,241 was from other Government Departments and £723,601 from industry, £613,592 in all being received by the National Physical Laboratory: the net increase on 1959 was £1,447,871. Grants to students amounted to £870,289, the number of research students in training being 2,377, of whom 942 (including 88 NATO awards) were new; advanced course studentships numbered 315 (of which 274 were new), first-year studentships 77, and research fellowships 75, of which 30 were held overseas and 45 in Great Britain, and 39 (including 21 NATO fellowships) were new.

Of the research students, 290 were in biology and biochemistry, 176 in chemical engineering, 747 in chemistry, 77 in electrical and 162 in other engineering, 143 in geology, 43 in the human sciences, 236 in mathematics and 503 in physics. Of the advanced-course students, 67 were in physics, 62 in mathematics, 20 in electrical and 42 in other engineering, 39 in geology, 28 in biology and biochemistry, 27 in chemical engineering and metallurgy, 25 in the human sciences and 5 in chemistry. All 77 first-year studentships were in chemistry, and chemistry (22), physics (21) and biology and biochemistry (18) claimed most of the research fellowships.

Grants for special researches totalled 525, of which 293 were new, amounting to £5,591,270; of these, 75 were in biology, 102 in chemistry, 37 in geology and geophysics, 3 in mathematics, 19 in astronomy, 65 in low-temperature work and investigations on the solid state, 60 (totalling £2,221,896) in nuclear physics, 90 in technology, 23 in the human sciences, and 24 (totalling £297,543) in space research. The report does not include the list of individual grants exceeding £1,000 or more, nor is the analysis of the research effort of the Department's research stations given in last year's report repeated.

---

* Department of Scientific and Industrial Research. Report of the Research Council for the year 1960. Pp. 65. (Cmnd. 1365.) (London: H.M. Stationery Office, 1961.) 4*s*. net.

Expenditure on the Warren Spring Laboratory was £402,854 gross, compared with £404,963 in 1959, and on the Torry Research Station, Tropical Products Institute and Government Chemist, which appear in these accounts for the first time, £177,860, £164,051 and £290,237, respectively. Otherwise, there are increases under all the separate heads of expenditure, the largest increases being in headquarters administration (£623,206 from £441,440); the National Physical Laboratory (£1,438,776 from £1,285,018); building research (£656,975 from £599,931); Geological Survey and Museum (£490,014 from £433,550); National Engineering Laboratory (£686,156 from £637,299); and road research (£718,056 from £618,763). Expenditure on fire research amounted to £158,441; on hydraulics research to £175,041; on radio research to £239,174; and on water pollution research to £137,100.

Annual grants to research associations amounted to £1,761,368 (£1,683,195 in 1959) and special grants to £17,823; £1,259,000 was contributed to the European Organization for Nuclear Research and £75,333 to NATO scientific schemes. Expenditure on headquarters overseas liaison increased from £113,929 to £132,684. Further progress is reported with the planned expansion of the staff, which rose by 3 per cent from 5,506 to 5,680 during the year, and it is estimated that, excluding stations transferred to or from the Department, the total staff has increased by just under 20 per cent during the past four years.

THE RADIO RESEARCH STATION, SLOUGH

THE Radio Research Station, Slough, gave visitors the opportunity of seeing some of its work during two open days on May 31 and June 1. Most of the Station's work is concerned with radio-wave propagation and with the fundamental properties of the ionosphere and the troposphere through which the waves travel. About half of the work is devoted to some aspect of experiments made on rockets and artificial satellites.

Among the exhibits concerned with the propagation of very-high-frequency waves through the troposphere was one which showed how the dielectric constant of the air had been measured continuously in an aeroplane. The measurement was made by determining the natural frequency of an open-ended electromagnetically resonant cavity. The measured distributions of dielectric constant were then related to certain aspects of radio wave propagation. Of other exhibits concerned with tropospheric propagation one showed a method for determining the azimuthal angle of arrival of waves propagated by tropospheric scatter from distances beyond the horizon, and another showed how the time-delays in multipath transmission over a distance of about 35 miles were being measured.

Equipment used for recording information about the ionosphere over Slough and over outstations at Falkland Islands, Singapore and Inverness was demonstrated. The results, together with those from other ionosphere observatories all over the world, are available for the use of all bona fide workers in the Station's World Data Centre. This is one of four set up in different countries by international agreement. One of the exhibits showed how the Research Station was making use of these recordings to investigate the nature of the ionosphere over the polar regions. Conditions of strong absorption (blackout) and of sporadic ionization at levels near 100 km. (*Es*) were shown to occur along spiral lines fixed in space relative to the Sun. When, as a result of the Earth's rotation, any given point on the Earth passes beneath one of these spirals, the appropriate phenomenon is observed. The two spirals, one for the blackout and the other for *Es*, curve in opposite senses, due, it is thought, to the fact that they are caused by the arrival in the atmosphere of particles of opposite sign. Another exhibit showed how the ionosphere over Halley Bay in Antarctica had varied throughout the International Geophysical Year.

The ionization produced in the ionosphere by the Sun's radiation varies throughout the day and the season as the angle of the Sun's rays, and possibly also the constitution of the atmosphere, changes. If changes caused by these two varying quantities could be eliminated the density of the ionization might be expected to be a measure of the intensity of the solar radiation. Methods for removing these variations were explained and the way in which the resulting 'ionospheric indices' varied with time were shown. One puzzling result was that the indices both for the *E* and *F* regions appear to have decreased steadily throughout the past 20 years even when the variations of the sunspot cycle have been removed.

The procedure was shown in which a digital computer was used to estimate the main parameters (height and peak electron content) of the *F* region from a knowledge of these quantities at a few key observing stations, and it was explained how this might help in the future for forecasting the nature of the ionosphere all over the world.

Once the world-wide *F* region is known, it is, in principle, possible to calculate the different rays by which waves will travel, on any frequency, from any one point to any other point on the Earth. The results of such calculations were compared with measurements of pulses received over the range of frequencies from senders in Malta and on Ascension Island. It is hoped that this kind of calculation, extended with the help of a digital computer, might lead to a simplified method for planning the frequencies used in point-to-point communications.

Another series of exhibits showed the work of the research station in the field of radio measurements. A resistive film inserted in a waveguide was used in an apparatus for the measurement of microwave power. This device had been compared satisfactorily with other standards from other laboratories and other countries.

Realization of the danger of intense radio-wave fields has led, recently, to a need for their measurement. A method of calibrating field-strength meters for these measurements was shown in which the intense field was produced in the space between the two plates of a 'strip waveguide'. In this way a field of the necessary intensity was produced from a comparatively feeble source of power and was confined to the guide, where it was harmless.

Other exhibits showed what was being done in research concerned with rockets and artificial satellites. Observations of the Faraday and Doppler effects on the waves emitted from satellites had led to deductions about the total electron content of the ionosphere overhead. Observations of the orbits of satellites were being used to make deductions about the density of the upper atmosphere and its variation.

An experiment to investigate the electron density in the ionospheric *D* region is to be performed in a rocket fired from Watheroo in Australia. This experiment will be done in collaboration with the University of Sheffield. The apparatus in the rocket will measure the parameters of a low-frequency wave-field set up above a transmitter radiating waves from the ground on a frequency near 200 kc./s. Part of the equipment was shown.

The Research Station is to collaborate with Canada and the United States in an experiment designed to investigate the upper side of the ionosphere. In this, satellites designed and launched by those working in the other countries will carry equipment to sound the ionosphere from above. The part of the Radio Research Station will be to receive telemetry from these satellites at Slough, Falkland Islands and Singapore, and to compare the results of the 'topside' sounding with the results of sounding made at these three places from the ground.

The Research Station is responsible for manning and running a station of the 'Minitrack' system set up by the Americans on a world-wide basis for the tracking of artificial satellites and the reception of their telemetry. The equipment is provided on loan by the Americans and is installed at a field site in Winkfield, about eleven miles from the Research Station. The visitors were taken there to see it. Measurements of position and records of telemetry made at this Station are sent back to America and are also available for the use of workers on the Station.

A World Data Centre for Rockets and Satellites, one of three, is run by the Station which is also responsible for tracking the position of the more important satellites for the use of optical and radio observers in Britain.

THE ROYAL AIRCRAFT ESTABLISHMENT, FARNBOROUGH

THE open days held at the Royal Aircraft Establishment, Farnborough, during June 9–10 were the first for six years. (The annual Air Show is, of course, that of the Society of British Aircraft Constructors, who hire the airfield for the occasion.) They gave a vivid impression of an Establishment that can afford to remain silent about its 56 famous years of service to scientific aviation (except through the single exhibit of a flying *S.E.5a*, the fighter designed at Farnborough of which Britain built 5,000 in the First World War), presumably because the present is so packed with excitement and achievement in the Establishment's main fields of transport aircraft, military aircraft, space, weapons, aircraft equipment and general research.

A central display hall, transformed from an aircraft hangar into a pavilion with flowers and fountains, summed up the whole display. It set out in its first illustrated stand the organization of the Royal Aircraft Establishment, with its headquarters at Farnborough, its second ultra-modern research centre and airfield at Bedford, and its well-equipped ranges for weapon trials. Subsequent stands, each devoted to one of the six main fields just noted, showed by models and highly informative backcloths how the different kinds of scientist and engineer in the Establishment make their different contributions to each. For example, study of transport aircraft problems was stated to include work on 'cabin conditioning', 'engine intake design', 'metal fatigue' and 'communications engineering' as four out of some thirty separate contributions—and similarly with the other fields. Two further stands showed the impressive range of major equipment for experimentation which the Establishment possesses to help it do its work, and the large-scale workshops, drawing-office and aircraft-servicing effort that lies behind the scientific achievements.

Both this central hall, and the 108 specialized scientific or technological exhibits, showed an Establishment pushing vigorously forward, with all its extraordinarily diverse activities concentrated on a few clearly defined objectives—to get air transport safer, cheaper, faster, more comfortable, more reliable, to get for the Army, Royal Navy and Royal Air Force a complete range of aircraft and weapons which will use the latest scientific advances to meet economically the needs of war as they are now envisaged, to develop continually improved aircraft equipment for navigation, reconnaissance, communications, power generation, automatic control and even landing, and to ensure that in spite of a late start Britain reaps the benefits of operations in space. Inquiries showed that the extent of 'space' activity, not only on the development of launching vehicles based on *Blue Streak* but also on the technology of satellites themselves, with special emphasis on a satellite system for world-wide communications, would almost justify a re-christening as the 'Royal Aircraft and Spacecraft Establishment'.

In advanced scientific research the variety of activity was astounding. For example, supersonic and hypersonic aerodynamics were to be expected, but the strength of the Farnborough school of low-speed aerodynamic research was equally evident, and remains equally necessary. The complexity of its subject-matter was exemplified by a wind-tunnel investigation of the effect of ground proximity on the lift of an aircraft model with swivelling jets, after the manner of the *Hawker P.*1127 vertical-take-off strike aircraft. Equally the 'slender-delta' designs of supersonic airliner have demanded for the solution of their landing and take-off problems a new aerodynamics, the extension of which into the unsteady 'gust case' was exemplified by an exciting experiment in which balsa-wood models were catapulted across a 24-ft. wide jet of air and their response in roll and yaw recorded by ciné-camera.

Another flourishing research school is in physics and chemistry of materials. The physical mechanisms of metal fatigue, including the details of crack development under cyclic loading, are now, in the main, scientifically determined, and are being rapidly related to the fatigue-life estimation of aircraft structures, showing, as one surprising result, that increase of temperature can sometimes extend fatigue life, because crack propagation in each cycle may halt sooner if plastic working is facilitated. Research on new materials has uncovered some impressive carbons with good strength and zero permeability, some new methods of construction in plastics reinforced with fibre-glass to give a strength-to-weight ratio 2·4 times better than 100 tons/in.^{2} steel, and a range of promising organic syntheses aimed at lubricants and polymers with improved high-temperature stability.

In the electronic field, an important new method of determination of the effective mass of charge carriers in semi-conductors was demonstrated, using observations of Faraday rotation, which was also shown modulating a beam of infra-red radiation at audio-frequencies. Promising circuits were exhibited, aimed at using semi-conductors to convert variable-frequency power from an aircraft's alternators to constant frequency. Research on aerials included the study of logarithmic-spiral forms at microwave frequencies, and some elegant work on corona breakdown on aircraft aerials at altitude. In the electronic equipment field, the miniaturized telemetry equipment, for transmitting pressures and other data to ground during weapon trials, stood out particularly.

Servocontrol is a well-known Farnborough activity. In the manned-aircraft field, it was interesting to see an aircraft being flown with all-electric signalling between the pilot's stick and the control surfaces. This is being used to facilitate a range of manœuvre demands. In the rocket field, the control of *Black Knight* by the swivelling of its two motors was demonstrated, together with equipment for stabilizing the attitude in space of the upper-atmosphere-research rocket *Skylark*. Equipment for studying the possible gyro-stabilization of a communications satellite so that its aerials will always point towards the centre of the Earth was also exhibited.

Research aimed at navigation and guidance was shown in impressive volume and quality. The propagation of very-low-frequency waves (of length around 20 km.) is now known to have remarkable stability as far as the antipodes even during magnetic storms, and research in a *Comet* aircraft flying from Farnborough has given good reasons to expect development of an airborne system for world-wide position determination within an error of at most 5 km. using only six ground transmitters. Inertial navigation has also been making extraordinarily rapid progress, with the Royal Aircraft Establishment again active, its longer-term researches being aimed, it appears, mainly at reduction in costs. Other titbits in this field were a tantalizing star-tracking demonstration and a glimpse of the future for high-speed computers in air traffic control.

It would be impossible to do justice to this huge exhibition in a short article, although a brief mention of the fascinating stands relating to water-drop or ice-crystal impact on aircraft, to new wind-tunnel techniques for aeroelastic research, and to rocket techniques for aerodynamic research at very high speeds, can scarcely be resisted. The days ended with experimental flying displays, showing among other things how the British army of the future may receive its supplies without parachutes, by low-level drops of equipment on special shock-absorbing skids, and how flight research is adding to our knowledge of the physical characteristics, and the effects on aircraft, of atmospheric turbulence.

Mr. M. J. Lighthill and his staff at Farnborough can be warmly congratulated, both on the story that they have had to tell and on the manner of its telling.

PETER SANDERSON

BRITISH BAKING INDUSTRIES RESEARCH ASSOCIATION

NEW LABORATORY WING

A NEW laboratory wing at the Baking Industries Research Station, Chorleywood, was opened on April 27 by Mr. Trevor Bowen, honorary president of Barkers of Kensington, and a former master of the Worshipful Company of Bakers.

In declaring the new north wing open, Mr. Trevor Bowen recalled the early days of the Research Association in 1947, when it had few members and a staff of only three, and, to indicate his appreciation of the services rendered by the Research Association, Mr. Bowen made a most generous gift of one thousand guineas as a contribution towards research.

The facilities of the new wing have been made essential by the growth in the Association's membership and activities. The work of the Association has outgrown the extra accommodation made available in 1951, when the present west wing was opened, and the need for additional and improved facilities has been a pressing one for some time.

The new accommodation consists of a two-storey wing running northwards from, and linked to, the original building of Chorleywood Lodge, designed to blend with the existing buildings and erected at a cost of approximately £40,000, including equipment.

The main feature of the ground-floor is the pilot-scale biscuit bakery and its associated laboratory. New pieces of equipment, built specially by members of the Research Association, are a model forced convection travelling oven by the Spooner Food Machinery Engineering Co., Ltd., and a De Vuurslag rotary biscuit cutter supplied by John Pelkman Engineering Co., Ltd. The biscuit section will thus have, virtually, a model biscuit plant which will enable the whole range of hard- and soft-dough biscuits to be studied. It is expected that this will enable previous work to be expanded on such problems of biscuit production as checking, or spontaneous cracking, in biscuits, on changes in biscuit dimensions in baking, and on the effect of various factors such as fat composition and storage conditions on the development of fat bloom on biscuits. The new equipment should also greatly facilitate the testing of biscuit flours and the development of standard procedures for this purpose. Sectioning and staining procedures have enabled a technique to be devised for investigating the starch, protein and fat distribution in biscuits and these investigations will be continued.

A new and well-equipped laboratory has been provided for the Organic Chemistry Section. This will give much-improved facilities for the work which has been in progress for some years on flour lipids, which is substantially supported by a grant from the United States Department of Agriculture. The work on lipids represents one facet of the attack on the problem of why flours differ in baking quality. Its immediate aims are to establish whether wheats of different varieties grown under identical conditions differ in lipid content, the influence, if any, of seasonal or environmental factors on the lipid composition of a single wheat variety and, finally, whether the lipid content or composition of a flour may be correlated with its baking properties. Also being studied are the fatty acid distribution in flour lipids, and methods for the separation of flour lipids in undegraded form.

These investigations, together with others in progress at the Research Station, will be greatly facilitated by the Buhler mill, which forms part of the equipment of the new Cereals Research Laboratory. This mill will provide much-needed facilities for milling wheat varieties on the site in connexion with the lipid project and other investigations, such as that of protein fractions being carried out in the new Physical Chemistry Laboratory. These provide another aspect of the problem of baking quality. Proteins of the gluten complex are being studied in the hope of establishing why wheats of similar protein content differ so markedly in this respect, and the work ultimately may lead to an understanding of the vast superiority of wheat protein over other cereal protein for bread-making. The present emphasis is on separation of gluten into its constituent proteins using starch-gel electrophoresis.

Also in the Physical Chemistry Laboratory are located the investigations into bread staling at present being pursued. These are concerned with those properties of wheat starch which influence the hardening of bread during the staling process with particular emphasis on the role of anti-staling agents. These agents increase the initial softness of bread and reduce the rate at which it hardens on ageing. Investigations of the interaction of anti-staling agents and starch are in progress in order to elucidate the basic mechanism of these effects.

An instrument and balance room has been provided on the first floor to house the more elaborate equipment used by all sections on different occasions.

At the southern end of the first floor the new Microbiology Laboratory extends the width of the building. There are a separate room for sterilization and another with filtered air-intake suitable for sterile techniques. The laboratory is concerned with all aspects of the microbiological deterioration of baked goods, but at present the work is mainly concerned with factors affecting mould growth in baked products, such as the effect of humidity, sugar concentration, and the degree of acidity or alkalinity of the mix. The use of mould inhibitors, such as propionic acid and its salts, as ingredients in bread and cake is also being studied. It is expected that legislation will shortly be passed to allow the use of these compounds, and the most effective ways of employing them and of overcoming side-effects, such as a reduction in bread volume, are being worked out.

Further facilities in the north wing are a combined office and laboratory for the Deputy-Director of Research, and another for the head of the Member Services Division, who is also responsible for applied research projects.

There is also office accommodation for two members of the newly formed Scientific Liaison Service set up to complement the work of the Industrial Liaison Service, which is staffed by trained bakers. The purpose of this Scientific Liaison Service (at present staffed by a chemist and an engineer) is to promote the application of the results of scientific research in the baking industry and to assess those problems in industry which require some research for their solution. These objectives are being attained primarily by personal visits and discussion, but also by lectures, demonstrations and collaborative experiments. A mobile laboratory has been equipped to take scientific apparatus to members' bakeries and has already proved its worth.

G. A. H. ELTON

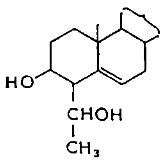
STEREOCHEMISTRY OF NATURAL PHENOLIC COMPOUNDS

THE aim of the Plant Phenolics Group symposium, held at the University of Bristol on December 16, was to discuss recent developments and current problems concerning the stereochemistry of natural phenols against the background of available methods for determining the stereochemistry of molecules.

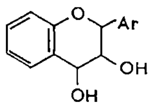
Dr. B. R. Brown (University of Oxford) dealt with the determination of relative stereochemistry.

The methods available for the determination of relative stereochemistry were illustrated by reference to the conformationally rigid, steroidal diol system (I) and to the conformationally non-rigid flavan-3,4-diol system (II). Infra-red measurements of C—O stretching frequencies enable reliable conclusions to be reached about the stereochemistry of the 3-hydroxyl group in (I) but not about the hydroxyl groups in (II), because of interference from aromatic vibration frequencies. Similarly, infra-red studies of hydrogen-bonding in (I) lead to reliable conclusions, but those from (II) do not, because of the conformational lability of the system. Ring formation to give carbonates or *iso*propylidene derivatives is diagnostic with (I) but not with (II), the *cis* and *trans* isomers of which both form cyclic compounds. In view of this, measurements of the rates of cleavage of flavan-3,4-diols with lead tetraacetate is in progress, a method which enables the *cis* and *trans* isomers of cyclohexane and other cyclic 1,2-diols to be differentiated. The method of molecular rotation differences has been applied with success to the steroids (Barton) and to the catechins (Freudenberg) and more recently by

Weinges[1] to correlate naturally occurring catechins, flavanonols, and flavan-3,4-diols (leucoanthocyanidins). The application of enzymic methods to sugars is well known and a recent investigation by Bokadia, Brown and Somerfield[2] indicates that it may have value when applied to polyphenols of the catechin type.



(I)



(II)

Prof. W. Klyne (Westfield College, University of London) described the determination of absolute stereochemistry.

The determination of the structure of an asymmetric natural product should not be considered as complete until its absolute configuration is known. The principal methods, with examples taken from different fields of organic chemistry, and chiefly from recent literature, are as follows:

(1) Chemical reactions, without displacement at the asymmetric centre, concerned: (*a*) degradations, for example, catechins (Hardegger *et al.*), cadinene (Herout and Šorm), and methymycin (Djerassi); (*b*) syntheses, for example, the conversion of representatives of the yohimbine–corynantheine–ajmalicine alkaloids and cinchona alkaloids into a common intermediate (Wenkert).

(2) Chemical reactions, with displacement at the asymmetric centre, concerned, for example, the classical studies of Ingold, Hughes and their colleagues on the steric consequences of nucleophilic substitution. Arguments by analogy include the work of Balenovic on β-aminobutyric acid, and of Witkop and of Sicher on ephedrine.

(3) Asymmetric synthesis (Prelog and Cram), for example, the catechins (Birch) and the diphenic acids (Mislow, also Berson).

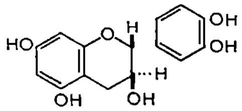
(4) Formation of quasi-racemates (Fredga), for example, the correlation of (+)-methylsuccinic acid and (−)-thiolsuccinic acid, which gave the first link between branched-chain compounds and the glyceraldehyde series.

(5) X-ray crystallographic methods do not, in general, distinguish between enantiomers, but an ingenious technique due to Bijvoet (Utrecht) which uses X-radiation of a wave-length which is partly absorbed by an atom in the crystal under examination permits a solution of the phase problem and determines the absolute configuration of the structure. This method, first applied to sodium rubidium tartrate, showed that by a fortunate chance the Fischer convention for glyceraldehyde is correct.

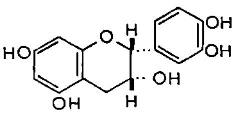
(6) Optical rotation evidence: (*a*) rotatory dispersion, (*b*) monochromatic rotations. All structural and stereochemical arguments which make use of optical rotations are based on analogy, and the usefulness of such arguments depends on the care with which analogies have been chosen. Recent instrumental developments have permitted the measurement of complete rotatory dispersion curves (that is, rotation : wave-length curves). Djerassi has found that "typical features of dispersion curves of alicyclic monoketones are on the whole only a reflexion of the immediate structural and stereochemical environment around that particular carbonyl group". A notable application of this principle was to the problem of the absolute configuration of the 'abnormal' diterpene, eperuic acid (Djerassi, F. E. King).

Dr. J. W. Clark-Lewis dealt with the stereochemistry of flavan derivatives.

The absolute configurations of the catechins were determined in 1957 and although the 2*R* : 3*S*-configuration of (+)-catechin (III) was unequivocally established, it was not until 1960 that the 2*R* : 3*R*-configuration of (−)-epicatechin (IV) received confirmation. The occasion of this symposium was therefore timely for reviewing the evidence for the configurations of the catechins. The diagnostic reaction for *cis*-flavan-3-ols is the elimination of toluene-*p*-sulphonic acid from tosyl esters, and for *trans*-flavan-3-ols is their rearrangement to 2-alkoxy-*iso*flavans; these two reactions have been used to characterize new catechins obtained by hydrogenolysis of leucoanthocyanidins and dihydroflavonols. Relative configurations of the catechins follow from the formation of enantiomeric 1-(3,4-dimethoxyphenyl)-3-(2,4,6-trimethoxyphenyl)-propan-2-ols after reduction of (+)-catechin and (−)-epicatechin methyl ethers with sodium and liquid ammonia. Reduction with lithium aluminium hydride and aluminium chloride mixture is accompanied by a 1,2-rearrangement and leads, after methylation, to formation of (−)-2-(3,4-dimethoxyphenyl)-3-(2,4,6-trimethoxyphenyl)-propan-1-ol from both diastereoisomers. It was shown that this rearrangement confirms the relative configurations of the catechins, and that it proceeds by benzyl-group migration. The absolute configurations of (+)-catechin and (−)-epicatechin are known from ozonolyses and from the application of Prelog's atrolactic acid method. The stereochemistry of several naturally occurring flavanoids can now be correlated with the stereochemistry of the corresponding catechins obtained by hydrogenolysis.



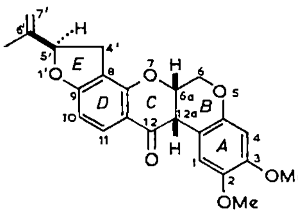
(+)-Catechin
(III)



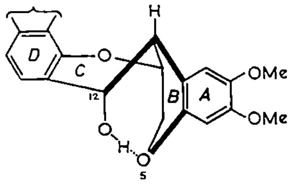
(−)-Epicatechin
(IV)

Dr. L. Crombie (King's College, University of London) described the absolute configuration of rotenone and its derivatives.

Work by Prof. G. Buchi (Massachussets Institute of Technology) and Dr. L. Crombie *et al.* has led to complete stereochemical proposals for the natural insecticide rotenone (V). By ozonolysis and oxidation the 5′ centre was extracted from the rotenone degradation product (−)-dihydrotubaic acid as (+)-3-hydroxy-4-methylpentanoic acid. The latter was related, by a series of transformations, to D-glyceraldehyde. Ozonolysis of the enol-acetate of 6′,7′-dihydrorotenone yielded the 6*a* centre as (−)-glyceric acid and the absolute configuration at 6*a* and 5′ is thus established. The B/C ring fusion of rotenone is the thermodynamically favoured form and this was shown to be *cis* by study of the stereoisomeric 12*a*-hydroxy*iso*rotenones, by hydrogenation evidence, and by infra-red methods. For example, the borohydride-reduction products of rotenone and its relatives show a hydrogen bond between the new 12-hydroxyl and the 5-oxygen which is possible only with a *cis*-fusion (cf. VI). The complete configuration of rotenone is thus (6*aS*, 12*aS*, 5′*R*) as in (V).



(V)



VI

Dr. W. D. Ollis, University of Bristol, spoke on the relative configuration of the rotenoids.

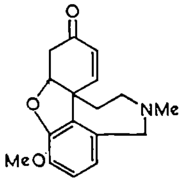
In collaboration with Prof. Carl Djerassi (Stanford University), it has been shown that the absolute stereochemistry of the eight natural rotenoids is closely related to that of rotenone (V). They all have the same relative stereochemistry at C_{6a} and C_{12a}; sumatrol and rotenone also have the same stereochemistry at $C_{5'}$. These stereochemical relationships have been established by optical rotatory dispersion studies on natural rotenoids and on derivatives of rotenone which were selected in order to assess the contributions of C_{6a}, C_{12a} and $C_{5'}$.

This work is complementary to that of Crombie and Büchi described in the preceding paper on the determination of the absolute stereochemistry of rotenone and indicate that the biosynthesis of the rotenoids is highly stereoselective. The stereochemical relationship between flavanoids, *iso*flavanoids and rotenoids, and possible biosynthetic implications were discussed.

Prof. D. H. R. Barton (Imperial College of Science and Technology, University of London) described alkaloid synthesis.

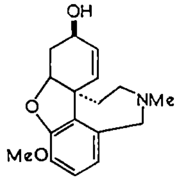
The biogenesis of many plant products may proceed through the oxidative coupling of phenolic precursors. In recent years several successful chemical syntheses have been based on this biogenetic idea; for example, oxidation of methylphloracetophenone and dehydration of the product gave the mould metabolite, usnic acid. Certain alkaloids may also be derived in principle by oxidation of suitable phenolic intermediates, the morphine group providing a particularly attractive example.

The structure of the Amaryllidaceae alkaloid galanthamine (VIII) was predicted on biogenetic grounds, and a chemical synthesis has now been completed. The hypothetical phenolic precursor was synthesized and its oxidation by a variety of reagents studied. Polymerization occurred readily but it was eventually possible to isolate the desired α,β-unsaturated ketone, narwedine (VII), in low yield. Reduction of narwedine gave a mixture of epimeric alcohols one of which was shown to be racemic galanthamine. A comparison of the physical properties of galanthamine and epigalanthamine showed that the hydroxyl group in galanthamine is hydrogen bonded to the ether ring oxygen atom, thus establishing the stereochemistry of these alkaloids. Narwedine racemized readily in hydroxylic solvents but crystallization of a mixture of (±)-narwedine (VII) and (−)-galanthamine (VIII) from ethanol gave (+)-narwedine. A study of this unusual phenomenon has led to the resolution of narwedine and galanthamine.



Narwedine

(VII)



(−)-Galanthamine

(VIII)

The biogenesis of Amaryllidaceae alkaloids is at present being investigated using precursors labelled with carbon-14. Preliminary experiments show that both tyrosine and the phenolic intermediate are incorporated into galanthamine in King Alfred daffodils.

INTERNATIONAL CONVENTION ON STARCH

THE annual International Starch Conference was once again held at Detmold, during April 26–28, and was attended by nearly 300 chemists from 25 nations. Twenty-five papers were presented to the meeting and they were classified as follows: (1) starch research; (2) industrial research; (3) derivatives.

A series of beautiful colour microphotographs were exhibited by Dr. A. H. Czaja (Aachen), showing the manner in which starch granules gelatinize in water. When suspended in a strong salt solution in the presence of I_2–KI the blue amylose fraction was seen to bleed out of the granule, leaving the violet amylopectin behind in the intact structure. No such bleeding of amylose was observed when the reaction was carried out in iodine-saturated water. Here the whole granule was stained violet throughout. When the granule was then damaged slightly by rubbing with a glass rod, the amylose blue colour was seen to develop. Potato, maize and rice starch behaved similarly.

When using a fluorescence dye, small starch granules were seen to fluoresce strongly (red) while large granules showed a weak green colour. No explanation of this behaviour, which is opposite to that expected, is yet known.

Acridine orange showed that granules of wheat starch were surrounded by a thin film of protein.

The renewed interest in the degradation of starch by physical means was discussed by S. Augustat (Potsdam-Rehbruecke), who had used a vibratory ball mill. In this machine the vessel does not rotate, but contains a large number of balls which are agitated with a frequency of 1,420 vibrations per min. The amplitude of the vibrations is about 2 mm., and the powder in the mill is kept in circulation by the airstream generated by the balls. After treating potato starch in such a mill for 5 hr. complete solubility in cold water was achieved together with a strong rise in reducing power. It was considered that this process may possibly have a future practical application.

The quantitative estimation of ether and ester groups in starch derivatives was described by Dr. R. J. van der Bij (Foxhol, Holland). A thin film of starch was cast on 'Pliofilm' and after removal the film was pressed between plates of rock salt. The estimation was carried out with the infra-red spectroscope, which gave a characteristic absorption band at 5·8μ. The intensity of the absorption was proportional to the degree of substitution, but a correction for the thickness of film had to be made.

The problems which arise through automation in the starch-producing industry were described by H. Runge (Hamburg). The starch industry is peculiar in that certain processes do not lend themselves to automation, so that an operative may be called on to perform his work in the conventional manner as well as by instrumentation. The main problem encountered in this industry was the education of a new generation of operatives who were able and willing to perform their tasks in this way.

A. Malyjev (Central Research Institute for the Starch and Starch-syrup Industry, Moscow) explained the use of the dextrose–sodium chloride double salt to facilitate the crystallization of dextrose in factories in the U.S.S.R. Dextrose syrup at 56° Brix was treated with 0·2 per cent sodium chloride (w/w) at 20° C. Crystallization was completed after 8 hr., and it was found that this was a much shorter period than experienced when crystallizing dextrose in the usual manner. The crystals obtained were larger and the yield (85 per cent) higher than normal. After crystallization the double salt was filtered off and decomposed in a syrup of 22° Brix, which had been cooled to 10° C.

The effect of certain cations on starch was discussed by G. Tegge and W. Kempf (Detmold) and Dr. S. Winkler (Berlin). Calcium and magnesium ions (such as occur in hard water) were found to lower the viscosity of starch pastes to a greater degree than sodium or potassium ions. It was maintained that the phosphoric acid ester of starch forms salts with these cations. It was claimed that the only true viscosity value could be obtained by having the ester in the free-acid form (called hydrogen starch). This form of starch was produced by washing the native, ungelatinized starch with $N/100$ hydrochloric acid for 10 min., followed by washing with distilled water for half an hour to remove the acid. Hydrogen starch was said to be unstable owing to slow autohydrolysis.

K. Pasirouk (Central Research Institute for Starch and Starch-syrup Industry, Moscow) described a new potato washing machine in use in Russian starch factories. Potatoes were freed from sand and grit by being shaken violently at 3,000 cycles/min. in a long stationary cylinder, through which a swift current of water passed. Potatoes vibrated with an amplitude of 5 mm. The machine dealt with 200 tons a day, each charge being 470 kgm.

A full account of the papers outlined above and of the remaining papers, together with the discussions which followed in each case, will be published in the journal *Die Stärke* in due course. E. Dux

THE NATIONAL INSTITUTE FOR RESEARCH IN DAIRYING

It is not always realized that the United Kingdom has one of the largest dairy industries in the world. Milk production in this country now exceeds 2,000 million gallons a year, and the milk has a value to the consumer of about £450 million, an amount of production which far exceeds that of many other well-known dairying countries such as New Zealand, Denmark and Holland. This vast and progressive British industry is continually increasing in efficiency, and much of the progress being made is directly attributable to the work done at the National Institute for Research in Dairying, the annual report of which for 1960 is now available*.

The Institute has grown greatly since the War. It now consists of ten main research departments, and has a staff of about 400 of whom some 30 per cent are members of the scientific and experimental officer grades.

The scope of the Institute's research programme is very great, ranging, as the report shows, from a study of many widely differing practical problems such as the use of slatted floors in the housing of dairy cattle and the types of chemical agents that can be approved for cleaning dairy equipment to basic scientific studies such as those of the Physiology Department on the pituitary gland and lactation, the biochemical properties of mammary gland mitochondria and the isolation, chemical structure and biological properties of the œstrogen mirœstrol.

No more than one or two of the many investigations now in progress can be referred to here. One particularly interesting example is concerned with the all-important question of the composition of milk on which, of course, the nutritive value of milk and milk products depends. It is now well known that much of the dietary energy absorbed by ruminants is absorbed in the form of the lower fatty acids which are produced in the rumen in different proportions from different types of feeding-stuffs. Collaborative work between two of the Institute's main research departments has shown that when isocaloric amounts of the lower fatty acids are given separately by ruminal infusion to lactating cows acetic acid increases not only the milk yield but also the fat percentage in the milk and the yields of fat, protein and lactose, whereas propionic acid has no effect on milk yield but increases the percentage of protein and decreases the percentage of fat. Butyric and lactic acids have no effect on milk yield but butyric acid increases fat percentage and lactic acid increases protein percentage. This type of information is already leading to a much better understanding of the factors that affect the composition of milk, and when further extended it should make it much easier than it is to-day to influence the composition of cows' milk within certain limits by suitable changes in the rations fed to the cows, a development which could be of far-reaching significance in the dairy industry.

Some of the other outstanding advances that are being made depend on the application of relatively new scientific methods to dairy problems. Work is being done, for example, on the differentiation and recognition of various strains and species of bacteria by paper chromatographic procedures, and the method is being applied in a detailed study of the bacterial flora of cheese. Then again gas chromatography is being applied to determine the volatile components of milk, and this may ultimately provide the basis of a rapid and reliable creamery platform test of milk quality. In another example a spectroturbimetric method has been devised which enables the mean fat globule diameter of homogenized milk to be rapidly determined. Indeed, it is abundantly clear from the report that every effort is being made to apply the most up-to-date scientific knowledge, methods and equipment to the art and practice of dairying in all its branches.

* National Institute for Research in Dairying. Report 1960. Pp. 164. (Shinfield: National Institute for Research in Dairying: University of Reading, 1961.)

The report includes a list which gives the titles and authors' names of the 165 papers which were published by members of the staff between October 1959 and September 1960. The Institute is to be congratulated on the variety, amount and high quality of the work reviewed in its report.

J. A. B. SMITH

FISHING IN MADAGASCAR

WITHIN the last decade, the fish *Tilapia melanopleura* has brought about a radical change in the diet and social habits of a large proportion of the population of Madagascar. Fish supplements the otherwise protein-deficient diet of the islanders, and fishing has become a useful and pleasant occupation practised every day by whole families.

The fish, along with other species of *Tilapia*, was first introduced by the Government ten years ago. The aim was to provide a source of much-needed protein to balance the Malgache menu of rice and manioc, fruit and a little honey, enlivened only occasionally by a small amount of meat or fish.

The *Tilapia* soon established itself in the rivers and lakes and multiplied rapidly. Fishing became popular. Encouraged by the success of this initial venture, the Government was stimulated to extend the output of fish still further by creating fishponds in the central part of the island where there is abundant water. Government agents went from village to village showing the inhabitants how to construct the ponds. By 1958 there were 40,000 village ponds; to-day there are 80,000, providing nourishing meals where formerly fish was seldom eaten.

A recent survey by Dr. Rudolph Kreuzer, Food and Agricultural Organization, Fisheries Division expert, shows that the average catch per adult is about 1·1 lb. of small fish each day, and even a small child can catch 4 lb. (*Sci. afrique*, 23; February 1961). Not surprisingly, the people who live near the rivers and lakes eat more fish daily than Europeans do in a week. But the quantities caught are related only to the fisherman's needs. There is still malnutrition in the dry areas of the island. Before this can be eliminated, it will be necessary to develop a fishing industry and overcome the distribution problems inevitable in the hot African climate.

A government pilot station on Lake Alaotra is already successfully producing smoked fish and fish meal. Dr. Kreuzer's investigations have shown that drying and salting would also be successful in the fishing villages along the western coast. There, shielded by a coral reef, a primitive technique, closer to hunting than fishing, is practised. First, a flotilla of outrigger canoes forms a semi-circle near the reef. By beating the paddles on the water, the men drive the fish inshore. Then the fishermen leap overboard to spear the catch in the water. Nets are used only to prevent the quarry escaping seawards.

Better methods of fishing and the development of economic methods of processing the catch would help towards correcting dietary deficiency where it still occurs. But formidable transport problems would still have to be solved, for dense bush isolates the west coast fishing villages from the rest of the island.

TERRESTRIAL EXOSPHERE AT HEIGHTS OF 1,000—1,700 km.

By MAX RÖMER

Sternwarte der Universität, Bonn

THE successful launching of the satellite iota 1, 1960 (*Echo* I), with its extremely small ratio of mass to area $m./A. = 10^{-2}$ gm./cm.^{2} first offered the opportunity of deriving atmospheric densities above a height of 1,000 km. For the time-interval August 12–December 19, 1960, it was possible to determine the densities for the heights 1,700 km. down to 1,000 km. Considering the large amplitude of the diurnal effect[1] and the relatively small eccentricity of the orbit it is impossible to use the density scale height H_ρ in the well-known air density formula by D. G. King-Hele, G. E. Cook and D. M. C. Walker[2]. The acceleration of a satellite is caused by the actual air density along the orbit. Therefore the 'individual orbital scale height' H characterizing a linear approximation to the logarithmic density function in the individual orbit was calculated[3]. For this calculation a model of atmospheric densities by H. K. Paetzold[4] was used augmented with the diurnal variation derived by W. Priester, H. A. Martin and K. Kramp[1]. The knowledge of the exact shape of the auxiliary model is not important because in the density formula only $\sqrt{H}$ is used. The computed densities hold for the orbital points of highest density, that is, for 14 hr. true local time.

The choice of the drag coefficient was discussed in detail[3] including the interaction of the charged satellite with the ionized component of the exosphere, and $C_D = 2{\cdot}5$ was adopted as a reasonable value[5]. According to R. W. Parkinson, H. M. Jones and I. I. Shapiro all orbital elements are disturbed by the solar radiation pressure during one revolution[6]. For orbits of small eccentricity the secular perturbation of the semi-major axis is very small. But for the calculation of air density by means of satellite accelerations all periodic variations of the orbital energy are important, the period of which is greater than the mean distance between consecutive orbital data. Considering the unequal time-intervals of acceleration and deceleration due to the non-uniform orbital

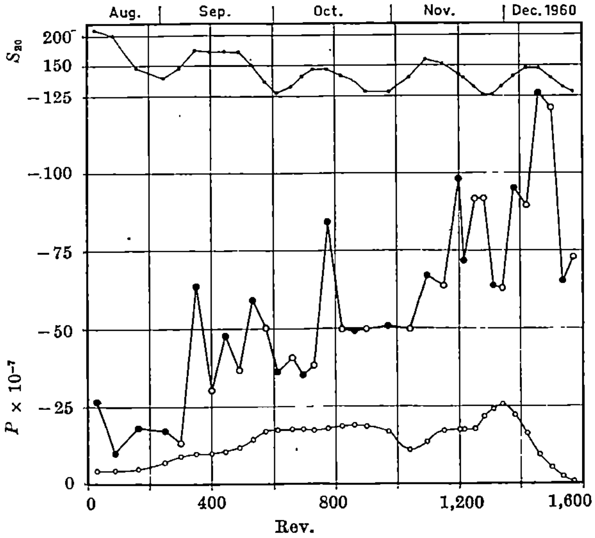

Fig. 1. Observed acceleration, acceleration due to solar radiation pressure and flux of solar 20-cm. radiation. The big circles of the curve in the middle of the diagram show the observed accelerations $\dot{P}_{\text{obs.}}$ of satellite *Echo* I. According to the different weight, mean values $\Delta P/\Delta t$ are represented by full circles and less weighted values dP/dt of the Bulletins of the National Space Surveillance Control Center, Bedford, Mass., by open circles. Accelerations due to solar radiation pressure $\dot{P}_{rp}$ are given by the small circles of the lower curve. The difference $\dot{P}_{\text{obs.}}—\dot{P}_{rp}$ yields the acceleration caused by aerodynamic drag. The flux of solar 20-cm. radiation S_{20} is shown in units 10^{-23} W./m.^{2} c./s. by the upper curve

velocity an approximate formula for the periodic perturbation of the period caused by solar radiation pressure (*rp*) was derived in co-operation with W. Priester:

$$\dot{P}_{rp} \simeq \frac{3 \times 8{\cdot}64 \times 10^4 \times P}{\pi} \cdot \frac{K \times \cos\theta_{\odot} \times e \times \sin(\omega - u_{\odot})}{m \times v} (\sin\Delta u_s - 2) \quad (1)$$

where P is period in days, $K = 330$ dyne, the product of area and radiation pressure if $\dot{S} = 2{\cdot}0$ cal./cm.^{2} min. $= 1{\cdot}4 \times 10^6$ erg/cm.^{2}/sec. is adopted for the total flux of solar radiation, e is orbital eccentricity, v orbital velocity in cm./s., m mass of the satellite in gm., $\theta_{\odot}$ the angle between the orbital plane and the line Sun–Earth, ω argument of perigee, $u_{\odot}$ angle of the Sun in the orbit measured from the ascending node and Δu_s is half of the angle of the Earth's shadow in the orbit. Fig. 1 shows that the acceleration due to solar radiation pressure cannot be neglected in the analysis of the observed accelerations of *Echo* I.

For the calculation of atmospheric densities the difference of the observed acceleration $\dot{P}_{\text{obs.}}$ and the acceleration due to solar radiation pressure $\dot{P}_{rp}$ was used. These densities were corrected to a flux of solar 20-cm. radiation $S = 170$ (unit 10^{-22} W./m.^{2}c./s.) using the standard reduction formula (ref. 7). The correlation of the observed density $\rho_{\text{obs.}}$ with the flux of solar decimetre radiation S was checked and the best representation is:

$$\rho_{\text{obs}} \propto S^{m(h)} \quad (2)$$

where $m(h) \simeq 2$ for altitudes 1,000–1,700 km. The calculated densities ρ_{170} for the standard flux $S = 170$ drawn in a ($\log\rho$, h)-diagram (Fig. 2) show a variation which can be explained by an 'annual' effect first found by H. K. Paetzold. The densities derived from *Echo* I by H. K. Paetzold[4,8], who uses a similar method which takes account of the large diurnal variation, are consistent within the limit of error if the influence of solar radiation pressure on the period is neglected. The values ρ_{170} were used by H. A. Martin and W. Priester[9] for expanding the density model (Bonn University Observatory model)[1] to 1,600 km. above the Earth ellipsoid.

Table 1. PHYSICAL PARAMETERS OF THE TERRESTRIAL EXOSPHERE

h 10^5 cm.	g cm./s.^{2}	$\log\rho$ gm./cm.^{3}	H_ρ 10^5 cm.	$\log p$ dyne/cm.^{2}	H_p 10^5 cm.	T/M °K.	M for $T = 1690$ °K.
600	819·5	0·140 – 15	111	0·142 – 5	123	121	14·0
700	796·5	0·770 – 16	120	0·806 – 6	136	131	12·7
800	774·5	0·427	132	0·504	154	144	11·3
900	753·4	0·115	145	0·252	182	165	9·7
1,000	733·1	0·818 – 17	160	0·042	228	201	8·1
1,100	713·6	0·555	179	0·896 – 7	307	264	6·5
1,200	694·9	0·330	205	0·772	398	333	5·2
1,300	676·9	0·135	237	0·677	515	419	4·1
1,400	659·6	0·970 – 18	281	0·600	647	513	3·3
1,500	642·3	0·831	333	0·539	795	614	2·7
1,600	626·9	0·712	399	0·490	957	721	2·3
1,700	611·5	0·609	484	0·448	1,129	830	2·0

If local thermodynamic equilibrium holds and the velocity distribution is Maxwellian[10] the connexion of the equation of state for ideal gases and hydrostatic equilibrium yields the differential equation:

$$\frac{1}{\rho} \times \frac{d\rho}{dh} = -\frac{m \times g}{k \times T} - \frac{1}{T} \times \frac{dT}{dh} + \frac{1}{m} \times \frac{dm}{dh} \quad (3)$$

where m is mean mass of particles, k Boltzmann's constant, T temperature and g acceleration due to gravity. If the exosphere is assumed to be isothermal above the critical height h_c, the gradient of temperature vanishes and equation (3) can be solved numerically with an assumed value of the mean molecular weight M and the temperature T at h_c as initial condition. The integration is stopped when the mean molecular weight begins to increase with increasing height and when a lower limit of $M = 1{\cdot}5$ is reached. The distributions of mean molecular weight passing between these two limits from the critical height up to 1,700 km. determine the temperature and the

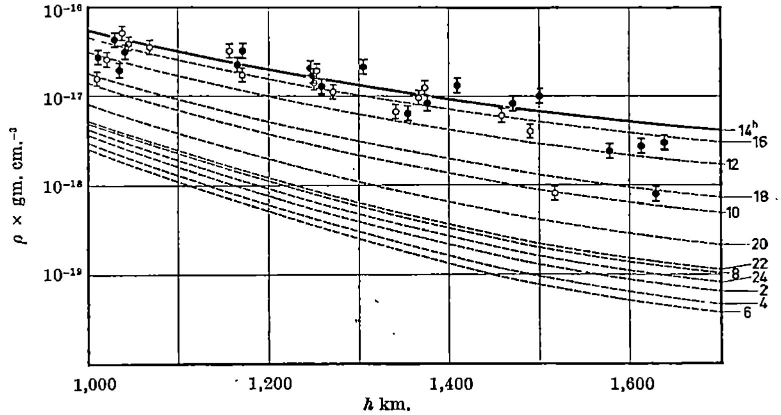

Fig. 2. Atmospheric densities at altitudes 1,000–1,700 km. above the Earth ellipsoid derived from satellite *Echo* I. The acceleration due to solar radiation pressure has been taken into account. The calculated densities (mean values represented by filled symbols, less weighted values by open symbols) hold for 14 hr. true local time and are corrected to mean solar activity ($S_{20} = 170 \cdot 10^{-22}$ W./m.^{2} c./s.). The 'fan shape' density model is the auxiliary model used for the calculation of the 'individual orbital scale height' H. The parameter of the curve gives the true local time. The time of year belonging to the densities is August 15, 1960, at $h = 1,640$ km. and December 18, 1960, at $h \simeq 1,000$ km.

lapse-rate of M in the exosphere. The temperature needed for the interpretation of the observed density distribution increases with increasing values of M at the critical height. For mean molecular weights of $M = 14, 16, 18$ at $h_c = 600$ km. the temperatures are 1,675° K., 1,900° K, 2,175° K. respectively.

One of the possible extrapolations of the density scale height $H_\rho = -\frac{dh}{d \ln \rho}$ leads to an isothermal exosphere with M = const. above 2,100 km. and to a pressure of $2 \cdot 02 \times 10^{-7}$ dynes/cm.^{2} at 2,100 km. The distribution of pressure can be calculated by:

$$p(h) = p(2{,}100 \text{ km.}) + \int_{h}^{2{,}100 \text{ km.}} \rho \times g \times dh \qquad (4)$$

The important physical parameters of the terrestrial exosphere are given in Table 1: acceleration due to gravity g, density ρ, density scale height H_ρ, pressure p, pressure scale height $H_p = \frac{p}{\rho \times g} = \frac{R \times T}{M \times g}$ and the lower limit of mean molecular weight M for T = 1,690° K. according to the H_ρ-distribution of the Bonn model. By means of the ratio T/M the mean molecular weight curve of an isothermal exosphere can be calculated for various temperatures. The unexpected small lapse-rate of the atmospheric density above 1,000 km. yields a rapid decrease of the mean molecular weight, that is, a rapid increase of hydrogen in the number density. For a detailed discussion of the problem see ref. 3.

I am grateful to Dr. W. Priester, who suggested this problem, for his co-operation and numerous discussions. Furthermore, I wish to thank the National Space Surveillance Control Center, Bedford, Mass., for supplying the orbital elements and the Heinrich-Hertz-Institut, Berlin-Adlershof, for the continuous dispatch of 20-cm. data prior to publication.

Note added in proof. According to recent investigations the orbital period of a satellite, which does not enter the Earth's shadow during one revolution, is not altered by solar radiation pressure. However, a comparison between the results plotted in Fig. 1 and the findings of R. W. Bryant (private communication) and of P. E. Zadunaisky *et al.* (*Smithsonian Astrophys. Obs. Spec. Rep. No. 61,* 1961) shows that formula (1) is a good approximation for the time-interval covered.

USE OF THE ROTATING HANGING MERCURY DROP IN ANALYSIS

Anodic Stripping using a Rotating Mercury Drop

By Dr. J. J. ENGELSMAN and A. M. J. M. CLAASSENS

Philips Research Laboratories, N.V. Philips' Gloeilampenfabrieken, Eindhoven

A HANGING mercury drop has been used by several authors, for example, DeMars and Shain[1] and Kemula and Kublik[2], for the analysis of metals forming amalgams with mercury after electrolysis. Usually the metals in the amalgam are anodically dissolved by applying a potential which varies linearly with time. On the basis of preliminary calculations involving the diffusion conditions in and around the mercury drop, we were led to believe that the time constant of the dissolution process should be of the order of a few seconds. Consequently, it should be possible to obtain separate dissolution peaks for each of the components of a multicomponent drop of amalgam, using a rate of voltage scanning such as is normally used in polarography (5 mV./sec.).

A rotating mercury drop electrode as described by Barendrecht[3] might be used for this purpose. Delahay *et al.*[4] mentioned the use of a similar electrode for anodic stripping, but they did not give experimental results. The platinum electrodes of Barendrecht and Delahay were gold-plated; according to Kemula *et al.*[5], gold interferes during stripping of zinc and cadmium amalgams.

We carried out experiments with an electrode consisting of a platinum wire of 0·25 mm. diameter sealed into the end of a piece of soft glass tubing 5 mm. in diameter and filed flush with the glass as described by Ross *et al.*[6]. The glass tubing was fused to a cylinder of a chromium-iron alloy connected to the shaft of a synchronous motor (3,000 r.p.m.). Electrical contact was made via a graphite sliding contact. The platinum electrode was centred to better than 25μ.

The platinum was cleaned by the method of Ross *et al.*[6] and a mercury drop was made by constant-current electrolysis in a concentrated solution of mercurous nitrate, 1 N in nitric acid, using a mercury pool anode (2 m.amp. 3 min.). During rotation of the electrode, the mercury drop remains attached to the platinum.

For trace analysis an anodic stripping voltammogram is run after a period of cathodic electrolysis of a few minutes. In Fig. 1 are shown the anodic current peaks of zinc, cadmium, lead and copper in a 10^{-3} M potassium chloride supporting electrolyte, 2×10^{-6} M in zinc, cadmium, lead and copper ions. The solution was electrolysed for 5 min. at $-1 \cdot 5$ V., the rate of scan during stripping was 5 mV./sec. and silver wire coated with silver chloride served as a reference electrode.

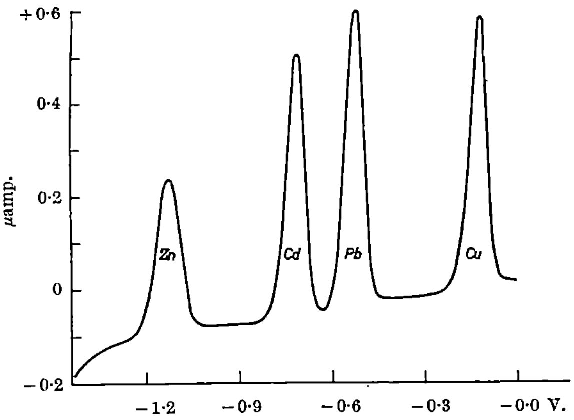

Fig. 1. Anodic current peaks of zinc, cadmium, lead and copper in 10^{-3} M potassium chloride, 2×10^{-6} M in the respective ions. Cathodic electrolysis: 5 min. at −1·5 V. vs. silver/silver chloride electrode. Rate of scan: 5 mV./sec.

The peaks are well separated and the areas of the cadmium, lead and copper peaks correspond to approximately 7×10^{-6} coulombs. The abnormal area and shape of the zinc peak may be attributed to the influence of platinum on dissolution of zinc from an amalgam, as mentioned by Kemula *et al.*[7].

The time-constant of about 4 sec. for the dissolution process allows the use of the rotating mercury drop for trace analysis of metal ions, described by van Swaay and Deelder (see following communication) as coulometric polarography. We intend to publish a mathematical treatment of this dissolution process in the near future.

Trace Analysis with a Rotating Hanging Mercury Drop

By Dr. M. van SWAAY and R. S. DEELDER

Laboratory of Instrumental Analysis, Technical University, Eindhoven

Kemula[1] and Engelsman (preceding communication) have described a technique for the analysis of trace metallic impurities. A solution containing the trace impurities as metal ions is electrolysed under polarographic conditions with a rotating mercury drop cathode. With the resulting drop of dilute amalgam, an anodic polarogram is recorded whereby the metals, dissolved in the mercury, return to the solution. The resulting anodic current peaks correspond to the composition of the amalgam, which, in turn, is determined by the cathodic electrolysis time and the composition of the sample electrolyte.

We should like to describe the technique as 'coulometric polarography'. A refinement of this technique will be described, together with some results showing the applicability of the method to the analysis of non-amalgamating metals.

Both Engelsman and Kemula use the same electrolyte for the cathodic and anodic electrolyses. If different electrolytes are used for the two parts of the cycle, we are free to choose one or more 'stripping' electrolytes for optimum separation of the anodic current peaks. Moreover, the properties of the sample solution are less critical, so that time of preparation may often be reduced. The results depicted in Fig. 2 demonstrate this feature. Here traces of zinc, copper, nickel and chromium in a sodium phosphate sample solution were determined without noticeable interference from the phosphate medium.

Merck analytical grade reagents were used throughout. Water was purified in a mixed-bed ion-exchange column. Supporting electrolytes were purified by prolonged electrolysis with a mercury pool cathode and stored under nitrogen in glass vessels connected to the electrolysis cell via 'Teflon'-glass stopcocks.

The rotating electrode consisted of a 0·5 mm. platinum wire forced through a 0·45 mm. hole in a small 'Teflon' plug contained in the 1½-mm. bore of a short length of glass capillary tubing. The complete electrode assembly was ground flush with fine emery paper. The capillary was mounted with wax on the shaft of a 3,000 r.p.m. synchronous motor running on ball bearings. Centring to within 5μ was achieved by trial and error with the help of a binocular microscope and a stroboscopic flash unit. Electrical contact was made via a small insulated mercury well at the top of the motor shaft.

At the electrode, a mercury drop was generated by electrolysis in a saturated solution of mercurous nitrate. The size of the drop was deduced from the time-integral of the generating current. A single drop could be used for a large number of experiments. By the judicious use of stopcocks, a complete set of experiments could be made without opening the system to the atmosphere.

In Fig. 1 a schematic diagram is given for a typical electrolysis programme. In Fig. 2 a typical anodic

voltammogram is shown for an analysis of 5×10^{-7} *M* each of zinc, cupric, chromium and nickel ions. In Fig. 3 the relation between peak area and sample composition is shown for the same four metals. The electrolysis programme is described in the legend.

The graphs for nickel and chromium ions show a slight deviation from linearity, which necessitates the use of a calibration curve. The anodic current peaks for these metals also show a tendency to broaden out rather than increase in height with increasing concentration. However, these effects do not seriously impair the usefulness of the method for these 'non-amalgamating' metals.

Attempts to extend the voltage-range beyond –1·5 V. (saturated calomel electrode) have so far been unsuccessful, because a large irreversible cathodic current began to flow at this potential. The nature of the corresponding electrode process is not quite clear, but two possibilities suggest themselves :

(1) The protecting nitrogen gas may not have been sufficiently free of oxygen to prevent reduction of oxygen to hydroxyl or peroxide, which may be responsible for the reduction current. It is unlikely, however, that this process accounts for all the current.

(2) The mercury drop may not have covered the platinum tip completely, so that reduction of hydrogen ions could take place at the exposed part of the platinum. This effect may be expected to show a strong dependence on the *p*H of the solution.

We intend to investigate both possibilities further in this Laboratory. If it proves possible to eliminate these interfering currents, the method will become useful for the analysis of a large group of metals in concentrations down to 10^{-9} *M* and possibly less.

FLUID–FLUID INTERFACES IN STEADY MOTION

By PROF. WALTER ROSE

University of Illinois, Urbana

GIVEN a capillary channel of constant cross-section (shape, area and orientation) and let a fluid, for example a wetting liquid, displace another immiscible one therefrom at a constant rate. The fluid–fluid interface, therefore, will be advancing at a steady velocity. I now set out to prove that this interface will everywhere and continuously have constant curvature, neglecting, as a simplification, distortions due to gravity.

The question is an important one, touched on briefly in the subject-matter and cited literature of the papers by Scriven *et al.*[1,2], and it is an essential one to the discussion of capillary flow if valid boundary conditions are to be assigned in solving the appropriate equations of motion[3].

By simple definition, a constant curvature surface (in the present case, a fluid–fluid interface having a closed-perimeter contact with the pore wall) is one where the sum of the reciprocals of the principal radii of curvature has the same value at every point on the surface. Elementary considerations lead to the realization that the curvature of a fluid–fluid interface at a particular point is proportional to the pressure difference between fluid pressures in each phase at contiguous points across the interface (that is, the so-called capillary pressure)[4].

Without loss of generality, let us limit attention to displacement phenomena in circular capillary tubes ; therefore, the interface either will correspond to the surface of a section of a sphere, if it is a constant curvature surface (as I believe), or the interface will have some other irregular shape (albeit with symmetry to the axis of the tube). In any event, since the motion is given as steady-state, the geometry of the interface will be fixed in time, without reference to the question whether or not a film (that is, a high concentration of surfactants) contaminates the interfacial region.

Suppose we think of a horizontal tube, and of a wetting liquid spontaneously displacing another less-wetting liquid of the same viscosity (assuring a steady motion) and density (avoiding all gravity constraints). The tube will be taken as very long, so that for most of the time when interface motion is occurring the losses of energy where the tube-ends are connected to inflow and outflow reservoirs can be neglected.

An observation of importance is that the axial component of fluid particle velocity will form (approximately) a parabolic profile in the radial direction at all distant positions ahead of and behind the advancing interface, whereas the interface itself moves as though the radial profile of the axial velocity component were (approximately) planar. The earliest references to this consideration which have come to my attention[5,6] are those cited by Gardescu[7].

As a term having phenomenological merit, we introduce the designation, 'fountain effect', to describe how the wetting liquid particles from the central pore space decelerate as they approach the slower moving interface region, acquiring a finite radial component of velocity as they spill over towards the wall region being vacated by the advancing interface. Correspondingly, a 'reverse fountain effect' is seen in the non-wetting fluid ahead of the interface, as fluid is displaced from the wall region and for the most part moves towards the tube axis, and as the fluid particles accelerate centrally ahead of the advancing interface.

Apparently, an integration of the equations of Navier and Stokes would yield a complete description of the fountain effect, and even though the boundary conditions may be specified, the integrability is hampered by the inherent non-linearities of the problem. Relevant numerical approximations have not as yet been attempted, as can be seen in the literature we have examined. In any event, the speculation of Barrer[8], as investigated experimentally in this laboratory at present[9], that the curvature of a moving interface depends on rate, undoubtedly is an important consequence of the fountain effect. That is, the changing interfacial curvature as rate of interface motion changes means that the capillary driving force is diminished effectively as an external stress is imposed to make the imbibing interface travel faster (that is, the rule of Le Chatelier).

Proceeding from Barrer's point of view, one might argue that the fast-moving fluid particles approaching the slower-moving interface along the central stream gain pressure energy in the loss of kinetic energy; hence, the interface is flattened, and in an extreme case the interface may even reverse curvature. This argument is incomplete, however, in simply emphasizing the Bernoulli condition without reference to viscous dissipation of energy; moreover, by itself no conclusion can be formed from the argument whether or not the moving interface has constant curvature throughout its areal extent.

Of interest in this connexion is the early work of Prandtl *et al.*[10], as extended later by Schlichting[11], who treated the somewhat corresponding problem of the transition in velocity distribution in the region near the entrance of a pipe. The boundary-layer methods, which are applied, have only limited application to the analysis of the fountain effect problem; however, some useful ideas are suggested by this cited work.

For example, taking the Lagrangian point of view (where the moving interface is thought to have a fixed position in the sense that the observer is moving with the same velocity as the interface), the wetting fluid will seem to have an outward component of radial velocity behind the advancing interface, and the non-wetting fluid will seem to have an inward component of radial velocity ahead of the advancing interface. Therefore, at all points on the surface of the interface the tangential component of velocity must be zero. This is because[12], if there is a two-dimensional solid film at the interface, the fluid particles of the two phases on each side must have the same tangential velocity as the film; likewise, if there is no film, the viscous stress will be continuous. Therefore, in either case, no tangential motion can occur in the interface region.

The foregoing continuity proposition is so important that it bears restatement: if all fluid particles in the near-vicinity of one side of the interface have positive components of radial velocity, while those of the second phase in the near-vicinity of the other side have negative components, and if the fluid particles of the two phases making up the interfacial region have the same tangential component of velocity, then this tangential component necessarily is zero at all points defining the interfacial surface.

Now, it will be readily apparent that, if the tangential component of the velocity vector is zero at the boundary of each phase forming the interfacial region, no pressure gradients exist in either phase tangential to the surface. In consequence, the capillary pressure differences between wetting and non-wetting fluids at each point in the interface region will have some constant value; hence the moving interface will be constant curvature throughout. This proposition, once accepted, leads to an obvious simplification in stating the boundary conditions necessary to analyse certain categories of capillary flows (Fara, H., and Rose, W., unpublished).

By parallel argument, we may conclude that interfaces in steady motion will be characterized by constant curvature no matter what the pore shape is, for tangential motions in the interface (whether it be a two-dimensional solid or liquid film) cannot occur. The criteria of Boussinesq[1], namely, the surface shear viscosity and the dilational surface viscosity, have no particular bearing on the problem at hand, but only enter into the description of the dynamics of interface movement during unsteady-states and/or when the cross-section of the pore channel changes with distance[13].

INTRACELLULAR DISTRIBUTION PATTERN OF RAT LIVER GLUTAMIC-OXALACETIC TRANSAMINASE

By Dr. HERBERT J. EICHEL and JOSEF BUKOVSKY

Department of Biological Chemistry, Hahnemann Medical College, Philadelphia

In recent years, serum glutamic-oxalacetic transaminase (GOT)-levels have been studied in many diseases in human beings and a variety of experimental states in animals[1]. Since it is possible that the increased serum GOT activity observed under abnormal conditions is a reflexion of tissue injury (hepatic, cardiac, etc.) resulting in the release of intracellular GOT which then enters the circulation, information concerning the intracellular localization of the enzyme is of basic interest. However, at the time the work described here was initiated (1958), detailed data were lacking on this point. Hird and Rowsell[2] had reported that rat liver mitochondria and supernatant fluid catalysed transamination between glutamate and aspartate. Müller and Leuthardt[3] found 32 per cent of the total homogenate GOT activity in the mitochondria isolated from isotonic potassium chloride homogenates of rat liver, but the enzyme was concentrated 2·3-fold in this fraction with respect to the original homogenate; the remainder of the activity was apparently present in an unseparated microsomal-supernatant fluid fraction.

In view of the incompleteness of these results, a study was undertaken in our laboratory[4] of the distribution of this enzyme among sub-cellular fractions obtained from rat liver and spleen homogenates by differential centrifugation. GOT activity was assayed by two procedures; that used most frequently was a modification of the spectrophotometric method of Karmen[5] developed for serum, and the other was the method of Greenwood and Greenbaum[6]. All tests were carried out at *p*H 7·6 in 0·033 *M* potassium phosphate buffer.

Normal male Wistar rats (200–400 gm.), fed a stock diet of 'Purina' fox chow checkers *ad libitum* to the time of death, were used. The animals were anæsthetized lightly with ether, bled by heart puncture, and the livers quickly excised and washed free of blood. Usually, 1–3 gm. of liver were removed from the left lateral lobe and homogenized with 9 vol. of ice-cold 0·25 *M* sucrose in a TenBroeck glass grinder. Homogenates were fractionated according to the method of Schneider and Hogeboom[7], with some changes[8], and nitrogen analyses on homogenates and all fractions were made by a micro-Kjeldahl procedure. About 50–70 per cent (average, 62 per cent) of the total GOT activity was found in the mitochondria, 20–40 per cent (average, 29 per cent) in the supernatant (soluble) fraction, and the remainder, due to mitochondrial contamination, in the nuclei (2 per cent) and microsomes (7 per cent). Only the mitochondrial enzyme had a higher specific activity on a nitrogen basis than that of the original homogenate (2 : 1), the specific activity of the supernatant being about equal to the homogenate activity. These results raised the following question: Is part of the enzyme associated with the soluble phase of the intact liver cell or does its recovery in this fraction represent an artefact caused by the procedure employed ?

We carried out several series of experiments[4] aimed at shedding further light on this problem. First, it was found that the unusual bimodal distribution pattern of GOT was unchanged when the fractionation medium was varied to favour the preservation of mitochondrial structure or for other reasons. Second, attempts were made to release GOT from the mitochondria by various physical and chemical treatments. Although exposure of the mitochondria (or homogenate) to the action of a Waring blendor, sonic oscillation, distilled water, or the detergent, 'Triton *X*-100', unmasked previously unreactive enzyme, that is, increased the measured GOT activity to varying degrees but several-fold in general, only a portion, at best, of the total mitochondrial activity was solubilized in the process. It should be emphasized that since the total activity of GOT of freshly isolated, intact mitochondria suspended in sucrose is at least doubled by such treatments, the activity of GOT recovered in the supernatant fraction is actually much less than 30 per cent of the total GOT present in the whole cell.

On the basis of these experiments and the specific activity data mentioned previously, it was concluded[4] that GOT is concentrated in the mitochondria of the normal rat liver cell. The picture was more equivocal concerning the activity found in the supernatant fluid. However, the fact that a significant amount of the enzyme was always present in this fraction, regardless of the nature of the homogenization and fractionation medium, spoke for the localization of some GOT in this part of the intact cell, and posed the question of whether there were any differences in the properties of the enzyme recovered in the mitochondria and supernatant. One step in examining this question is to investigate the activities of the enzyme in response to certain physiological stresses. In preliminary experiments, we studied the effects of starvation (72 hr.) and whole-body X-irradiation (700 r.) on the specific activities of GOT in mitochondrial and supernatant fractions of rat liver. While there was some indication that the activities of the two fractions responded differently, particularly after irradiation, the small number of animals involved precluded the drawing of definite conclusions. Interesting observations bearing on this question have been reported recently by Fleisher *et al.*[9] and Rosenthal *et al.*[10]. By a paper electrophoretic technique, the former authors demonstrated two fractions of GOT activity in water extracts of human and dog heart and liver minced in a blendor. One fraction migrated towards the anode and showed the known characteristics of serum GOT, while the other migrated towards the cathode and exhibited different affinities for α-ketoglutarate and L-aspartate and a different *p*H-activity curve. In our work[4], an attempt had been made only to differentiate the readily measurable mitochondrial GOT from that part of the mitochondrial activity which was unmasked and solubilized on blending, by assaying GOT at various *p*H values between 5·4 and 8. No difference was observed. Although the effect of *p*H on the activities of the supernatant and mitochondrial enzymes was not investigated, we entertained the possibility that the bifractional distribution of GOT might be related to the observation of Fleisher *et al.*[9]. Experimental support for such a relationship appeared in the recent abstract of Rosenthal *et al.*[10]. In agreement with our findings, although a completely different enzyme assay was used, they reported that GOT was found in the mitochondrial (70–80 per cent) and soluble fractions prepared from 0·25 *M* sucrose homogenates of rat liver. Furthermore, they indicated that the mitochondrial and soluble GOT activities of rat liver closely resembled the cationic and anionic forms of the enzyme described by Fleisher *et al.*[9] with respect to *p*H-activity curves and relative affinities for aspartate and α-ketoglutarate.

Regarding the intracellular localization of the enzyme, May *et al.*[11] recently found 45 per cent of the total GOT activity of rat liver homogenate in the mitochondria, 17 per cent in the supernatant fluid and 33 per cent in the nuclear fraction. An appreciable amount of GOT was also recovered in the soluble fraction prepared from rat brain homogenate[11]. We have shown that while GOT is apparently concentrated in the mitochondria of rat spleen[12], considerable transaminase activity is present in the supernatant fraction obtained from 0·25 *M* sucrose homogenates of this organ. It would seem that a bimodal distribution pattern of GOT is characteristic of many tissues, and it would be of interest to determine if the enzyme also exhibits chemical differences in the two fractions from tissues other than liver. In this connexion, it should be noted that the cationic and anionic forms of GOT were found in both heart and liver[9].

Fleisher *et al.*[9] showed that serum from several patients with myocardial infarction and viral hepatitis contained only small amounts of cationic GOT. From this, it might be inferred that in these diseases increases in serum GOT result chiefly from the release of the soluble, anionic intracellular GOT rather than the particle-bound, cationic enzyme. This would be consistent with the observation already made that, at least in rat liver, mitochondrial GOT is released in soluble form only after considerable structural damage to the particles. In this respect it is to be noted that the cationic enzyme was demonstrated in soluble preparations made by treating tissues in a blendor[9]. We have found that treatment of rat liver mitochondria (0·25 *M* sucrose) for increasing periods, either in a Waring blendor (2–10 min.) or sonic oscillator (5–20 min.; Raytheon model *DF* 101, 10 kc.), followed by centrifugation of the mitochondria for 1 hr. at 150,000*g*, renders soluble increasing amounts of the total mitochondrial activity present after treatment. However, from our experiments it would appear that about half the enzyme remains firmly bound to the mitochondrial membranes, and possibly the cristæ, and to attempt to release more, at least without special care, might invite denaturation of the GOT. Hence caution should be exercised in assessing and assigning significance to the proportions of the two forms of GOT present in extracts of blended organs[9].

Finally, it may be necessary to re-evaluate past studies in which liver homogenate GOT activity was examined in animals subjected to a variety of experimental conditions, that is, administration of hormones, instillation of toxins, exposure to ionizing radiations, effect of dietary deficiencies, carcinogens, etc. For example, since the soluble enzyme represents about 30 per cent or less of the total homogenate GOT of fresh preparations in sucrose, it can be calculated that as much as a 75 per cent decrease in its specific (or total) activity would yield only a 23 per cent decrease in the specific (or total) activity of overall homogenate GOT, provided there are no changes in the nitrogen content.

This work was supported by a contract (*AT* 30-1-2118) from the U.S. Atomic Energy Commission.

PHARMACOLOGICALLY ACTIVE SUBSTANCES PRESENT IN THE CENTRAL NERVOUS SYSTEM

By Dr. PAUL V. BUDAY

Department of Pharmacology, University of Rhode Island, Kingston, Rhode Island

PSYCHOPHARMACOLOGY is a new interdisciplinary science. It attempts to correlate mental aberration, emotional disturbance, and behavioural changes with modifications in the normal biochemistry of the central nervous system.

In an attempt to interrelate brain function with the psyche (mind) a number of basic propositions must be acquiesced. Thus, the thesis of psychopharmacology rests upon the concept that the brain and psyche, although distinct entities, are actually intimately associated and mutually dependent. It adheres to the principle that animal behaviour is a consequence of a dynamic equilibrium between a primitive, emotional and instinctual system (rhinencephalon), and a recollective, rational and cognitive mechanism (cerebrum). Psychopharmacology also asserts that emotion may very well be a result of cortical disorganization, and that biochemically induced changes in the central nervous system, via drug action, will modify psychic reactions.

This concept of mind–brain interdependence is not novel. In the sixth century B.C., the Greek physician Alcmaeon taught that the brain was the organ of the mind. To-day, the mind is, in certain respects, still considered to be the subjective expression of the living brain. Certain psychotogenic (hallucinogenic) drugs, for example lysergic acid diethylamide (LSD), mescaline, etc., provide an opportunity to readily induce a reversible model psychosis which, at least superficially, mimics schizophrenia, thus furnishing a closer introspection into possible psychopathological mechanisms.

A host of phrenotropic agents has been introduced into the armamentarium of the psychiatrist and physician in the past several years. These medicaments are believed to act, in the main, by way of certain substances found in the central nervous system. The substances thus far posited to be concerned with brain and mental activities include: adrenaline, noradrenaline, dopamine (3-hydroxytyramine), 5-hydroxytryptamine (5-HT), histamine, acetylcholine, γ-aminobutyric acid (GABA), adrenochrome, and substance '*P*'. Structural configurations for these chemical materials are depicted in Fig. 1.

Also intimately concerned are the sundry enzymes which synthesize and biotransform these biogenic substances. It appears that the neuro-hormones following synthesis are stored, physiologically inert, in certain cytoplasmic organelles and protected by certain intracellular barriers from enzymic catabolism. Following release, these substances become physiologically active, react with some cellular or

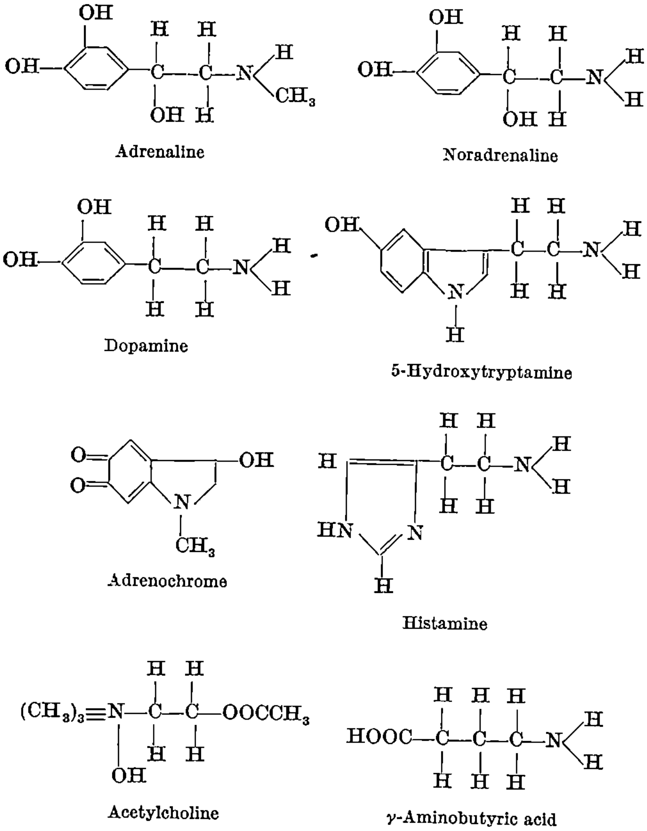

Fig. 1. Graphic configurations of some centrally active compounds

plasmatic membrane receptor, and thence regulate neuronal transmission or other functional processes. Biotransformation of the neuro-hormone then occurs via a specific enzyme system with subsequent termination of the substance's excitatory or inhibitory effects.

The central distribution of the neuro-hormones is well documented. The brain distribution of noradrenaline, the precursor of adrenaline, is disproportionate; highest concentrations are found in 'primitive' brain sites, namely, the hypothalamus, area postrema, medullary reticular formation and medial thalamus. Adrenaline, in lesser amounts, follows this distribution rather closely. Dopamine is located in highest concentrations in the corpus striatum, where peculiarly its metabolite noradrenaline is found only in minor quantities. Conversely, brain loci, for example the hypothalamus, replete in noradrenaline and its biocatalyst, dopamine-β-oxidase, contain paucid quantities of the parent molecule. 5-HT, synthesized from 5-hydroxytryptophan by the agency of aromatic L-amino-acid decarboxylase, follows the localization of noradrenaline rather closely. It is significant that only 1 per cent of the 5-HT content of vertebrates is found in the brain. The area postrema contains relatively high levels of 5-HT, but strangely enough no enzyme for its synthesis has been discovered here. Peripherally ubiquitous histamine is found in significant amounts solely in the hypothalamus and cerebellum, but histaminergic synapses have not been identified. Acetylcholine, reported by Pfeiffer *et al.*[1] to be derived from the naturally prevailing amino-alcohol dimethylaminoethanol, has been discovered particularly in the cerebral cortex, pons, thalamus, basal ganglia and other brain nuclei. An interrelationship between acetylcholine metabolism and that of adrenaline may exist for, theoretically at least, the monomethylaminoethanol chain cleaved from the latter compound may serve as a basis for choline synthesis[2]. GABA, a component of Florey's factor I, and manufactured via the agency of *l*-glutamic acid decarboxylase on glutamic acid, is present predominantly in the rhinencephalon ('visceral brain'), medulla, pons, and cortex. Adrenochrome, the highly labile indole oxidation product of adrenaline, has been discovered in erythrocytes and heart, and following convulsions, in brain tissue[3]. Substance '*P*', a biologically active polypeptide, has been detected in the intestines and brain, and in the latter especially in the basal ganglia, thalamus, hypothalamus, area postrema, and spinal cord.

A number of functions have been ascribed to these centrally active substances and the *modus operandi* of the various phrenotropic medicaments is largely predicated on their ability to modify the metabolism or receptor binding sites of these hormones or their metabolites. Hess[4] has postulated the existence of a subcortical (hypothalamic) integrating system composed of two reciprocally antagonistic divisions, namely, the 'ergotropic' and the 'trophotropic' nervous systems. The former mediates arousal, and an alerted mental state, skeletal muscle hypertonia, and an exaggeration of sympathetic activity. The latter centre, and anatomically the more anteriorly disposed, is concerned with sleep, apathy and psychic depression, a diminished skeletal muscle tone, and increased parasympathetic activity. Brodie and Shore[5] theorize that free (active) 5-HT and noradrenaline act as synaptic mediators for the trophotropic and ergotropic nervous systems repectively.

Marrazzi[6] has shown that adrenaline, noradrenaline, and 5-HT, as opposed to adrenochrome, are potent intercortical synaptic inhibitors, and he postulates that certain mental disturbances result from an imbalance between inhibition by adrenaline, noradrenaline or 5-HT and facilitation by acetylcholine of central synaptic, cholinergic transmission. Although acetylcholine activates Renshaw cells in the spinal cord, its, noradrenaline's, and 5-HT's inertness following electrophoretic application to medullary and reticular formation neurons implies a non-transmitting role for these substances in these particular areas[7].

Woolley and Shaw[8] have suggested that certain mental disturbances are caused by a metabolic deficiency of brain 5-HT. They have described a rather novel *in vitro* excitant action of this neurohormone on cortical oligodendroglia, and they hypothesize that 5-HT serves to augment cerebral metabolism through this neurotonic mechanism. Unfortunately, the careful clinical results of Feldstein *et al.*[9] do not support the concept of a relationship between 5-HT metabolism and acute or chronic schizophrenia.

The physiological significance of centrally partitioned histamine is still obscure. Indirect evidence for its participation in mental activity is exemplified by the antihistaminics, a number of which possess potent central actions. More direct evidence is gleaned from reports that histamine (and its methylated derivatives) are amine oxidase inhibitors.

Further, certain monoamine oxidase inhibitors affect histaminase (diamine oxidase) activity irreversibly. Histamine appears to be a natural synaptic inhibitor similar to 5-HT. Adrenaline blocks *l*-histidine decarboxylase[10], the enzyme responsible for the biosynthesis of histamine, and it may be that this hormonal effect provides a negative servo-mechanism for the regulation of central histamine-levels.

Feldberg[11] relegates a synaptic transmitting (facilitating) role to acetylcholine in the autonomic and central nervous systems. Because of this action on brain stem reticular formation synapses, Himwich and Rinaldi[12] propose that elevated brain concentrations of acetylcholine may exert antischizophrenic actions.

GABA, an amino-acid metabolite, is a synaptic and neuronal inhibitor. Purpura *et al.*[13] feel that this material is a transmitter substance in the sense that it acts as an inactivator of synaptic depolarization. It has been suggested that it may well be involved in neuro-excitability and in the etiology of certain brain abnormalities, for example epilepsy. GABA may also subserve the action of certain convulsive drugs, and the observation that monoamine oxidase inhibition elevates free brain GABA-levels tempts one to speculate that this explains the mechanism of the anticonvulsant action of certain 'psychic energizers'.

Hoffer[3] postulates that adrenochrome (chemically similar to LSD), or dihydroxyindole catabolites of abnormal adrenaline oxidation, are causes of schizophrenia. This concept, however, has been considerably criticized and this worker's findings have not been consistently substantiated. Adrenochrome may still have significance, nevertheless, for this hallucinogen is, at least *in vitro*, an inhibitor of both glutamic acid decarboxylase and cholinesterase.

Substance '*P*' is given a neuro-active role in the dorsal horns of the spinal axis, and a non-cholinergic transmitting function in the autonomic nervous system. It has been likened to a type of 'physiological tranquillizer' because of its meprobamate-like polysynaptic inhibitory properties in the central nervous system.

Vitally concerned with the action of the central neuro-hormones, especially the biogenic catecholamines and 5-HT, are the enzymes responsible for their biotransformation and inactivation. Monoamine oxidase is a prime example of such a biocatalyst the activity of which can be modified or destroyed by drug action with either a consequential deviation in normal metabolic pathways followed by its substrates or by a pile-up of these compounds. Monoamine oxidase is widely distributed in the animal body and is primarily located in mitochondria. Centrally, the enzyme is normally found where 'true' cholinesterase-levels are low, namely, the lenticular nucleus, hypothalamus, and pyramidal tracts. The primary functions assigned to monoamine oxidase are the metabolism of the relatively inert metanephrines[14,15] and other O-methylated catecholamine metabolites, and of degradating 5-HT to 5-hydroxyindoleacetic acid[16]. Dopamine, formed from dihydroxyphenylalanine by the action of aromatic L-amino-acid decarboxylase, is a better substrate for monoamine oxidase than noradrenaline, and hence enzyme inhibition by administration of a 'psychic energizer' shunts the metabolic pathway in favour of one catalysed by catechol-O-methyltransferase with the consequential accumulation of 3-methoxytyramine. This latter enzyme has been recently given the principal task of converting noradrenaline and adrenaline to the respective metanephrines[17,18], monoamine oxidase notwithstanding. Spector *et al.*[19] suggest that the latter enzyme may control cellular 5-HT and noradrenaline-levels, while catechol-O-methyltransferase inactivates blood-borne catecholamines. However, Belleau *et al.*[20] claim, rather convincingly, that noradrenaline is not acted on by monoamine oxidase at adrenergic effector cell sites. As may be noted, the implication of aromatic L-amino-acid decarboxylase in the formation of both the catecholamines and 5-HT leads one to believe that a closer correlation exists between the metabolic disposition of the catecholamines and 5-HT than heretofore suspected.

In summary, a number of pharmacologically active substances naturally occurring in the central nervous system have been briefly characterized and their potential physiological functions described. It seems, in retrospect, rather significant that of all the substances postulated to officiate as neuro-mediators or incriminated in the etiology of mental illness, only acetylcholine possesses neuronal and synaptic facilitating properties. It would appear that acetylcholine is the driving force in the nervous system whereas the remaining substances simulate physiological brakes. The phrenotropic agents widely employed in the pharmacotherapy of various forms of mental illness obviously modify brain biochemistry, some perhaps via mitochondrial receptor attachment[21], with apparently consequential effects on the psyche. However, it would be rather premature and naïve to hope that contemporary physiological, biochemical, and even psychopharmacological techniques of studying and modulating brain function will instigate dramatic and important insights into psychic activities. This problem is knotty and may perhaps have no solution as presently assailed. Nevertheless, break-throughs into this twilight zone bridging mind and brain may be possible if studies are performed with determination and if moderately permeated with imagination.

ANALYSIS OF THE THYMUS INFLUENCE IN LEUKÆMOGENESIS

By Dr. J. F. A. P. MILLER

Chester Beatty Research Institute, Institute of Cancer Research: Royal Cancer Hospital, London, S.W.3

THYMECTOMY markedly reduces the incidence of lymphocytic leukæmia in mice which would otherwise develop the disease spontaneously[1], or following exposure to ionizing radiations[2], chemical carcinogens[3] or virus inoculation[4]. Grafting thymus tissue to thymectomized mice restores the susceptibility to the development of lymphomas[1,3,5,6]. Thymectomy might prevent leukæmogenesis by effecting removal of one or more of the following: (*a*) the source of a leukæmogenic virus (either present from birth or activated by external leukæmogens); (*b*) the site of multiplication of such a virus (assuming that multiplication is a prerequisite for leukæmia induction); (*c*) the only type of cells capable of undergoing leukæmic transformation; (*d*) the source of a humoral factor involved in leukæmogenesis.

Presence of Leukæmogenic Virus in Non-Thymic Tissues

Evidence has been presented in previous papers[6,7] to show that the thymus does not act by simply providing the source of a leukæmogenic virus. Recovery of the agent from non-leukæmic tissues of virus-infected thymectomized mice[7] and restoration of incidence of lymphoma in such mice by grafting thymuses from normal mice as late as six months after thymectomy[6] strongly suggest that the virus is widely distributed in its host and not simply confined to the thymus. These results have recently been confirmed by other workers[8].

Virus Multiplication in Thymectomized Mice

It is possible that a leukæmogenic virus must reach a critical concentration before it can induce leukæmia in its host and that multiplication can only occur in thymus tissue. The question whether virus can multiply outside thymus tissue is being studied in this laboratory. Extracts of non-leukæmic tissues of thymectomized, virus-inoculated mice have been injected into successive generations of thymectomized mice after the operation. Since it has been shown that new-born or suckling mice are more susceptible to leukæmic filtrates than adult mice[9] it was decided to perform the operation of thymectomy in the first week of life. The technique used for baby mice was similar to that employed in this laboratory for adult mice[6], and the immediate operative mortality was no higher than 15 per cent. Subsequent mortality, however, was very high in mice that had been thymectomized at 1 day of age, more than 50 per cent of these dying between 2 and 4 months (whether they had been inoculated with virus or not), suggesting that the thymus at birth may be essential to life. Mortality at 3 months of age was much lower in mice thymectomized between 3 and 5 days of age. A group of mice thymectomized at that age were inoculated with leukæmic virus one day after the operation and killed 2–3 months later in order to prepare extracts from their spleens, livers and brains. Checks were made for the total absence of thymus tissue at death. The extracts were inoculated into a group of intact 3–5-day-old mice and into a second group of 3–5-day-old thymectomized mice. Extracts were prepared from the latter when they were about 3 months old and were inoculated in turn into further groups of intact and thymectomized baby mice. The incidence of lymphomas in the intact mice receiving the extracts at each generation is recorded in Table 1.

Table 1. LEUKÆMOGENESIS IN INTACT *C3Hf/Gs* MICE BY VIRUS SERIALLY PASSAGED THROUGH THYMECTOMIZED MICE

Inoculation given	No. of intact mice treated	Leukæmia incidence (per cent) and age in months
Passage *A* filtrate	26	73 (3–6)
Virus passaged once through thymectomized mice	10	80 (3–6)
Virus passaged twice through thymectomized mice	8	63 (4–6)
Virus passaged thrice through thymectomized mice	11	73 (3–7)

Only preliminary results from three generations are available, and these suggest that the leukæmogenic virus has not been lost by serial transfer through thymectomized hosts. The possibility, therefore, remains open that multiplication might occur in extra-thymic tissues. Such extra-thymic multiplication is not accompanied by neoplastic transformation in lymphoid cells, and, as a corollary, it may be that only replication within the thymus can be associated with leukæmogenesis.

Origin of Leukæmic Cells

The next problem to be considered is whether the thymus acts as a source of potentially malignant cells. It is possible that thymus lymphocytes differ from other lymphocytes in their susceptibility to neoplastic transformation. Experiments employing thymectomized hosts either genetically[8,10,11] or immunologically[12] tolerant of foreign thymus grafts have been set up by various workers in an attempt to settle this question. The results depended on the transplantation behaviour of the lymphoid tumour arising from the grafted thymus. In some cases the tumour behaved as if it had originated from lineal descendants of cells regenerating from the donor thymus tissue[11,12], which could then be assumed to have acted as a source of potentially malignant cells. In other cases, however, the neoplastic cells had the immunogenetic character of host-type cells[10,12] which must have populated the graft. Transplantation behaviour of tumour cells that have resided in an F_1 environment is not always clear cut, especially when the parental strains do not differ at the H-2 locus, and is always open to criticism in view of the phenomenon described by Barrett and Deringer[13].

The problem of the origin of leukæmic cells has recently been studied here in $(AkXT_6)F_1$ hybrid mice the cells of which can be identified at metaphase by the presence of an unusually small chromosome. The hybrids were inoculated at birth with leukæmic filtrate, thymectomized at 1 month of age and grafted subcutaneously with an intact thymus from a healthy 1-day-old *Ak* or T_6 mouse. The tumours developing in the graft were transplanted to *Ak*, T_6 and F_1 mice and also analysed cytologically for the presence or absence of the T_6 marker chromosome. Preliminary results are shown in Tables 2 and 3, from which it is apparent that: (*a*) the *Ak* thymus is much more effective than the T_6 thymus in restoring susceptibility to lymphoma development; (*b*) leukæmic cells arise in most cases from lymphoid cells of the host, suggesting that the thymic influence responsible for the leukæmic change is a non-cellular indirect one.

Table 2. Incidence of Lymphoid Tumours in *Ak* or T_6 Thymuses Grafted to Virus-infected $(AkXT_6)F_1$ Mice

Treatment given	No. of mice in group	No. of mice with lymphoid tumours and age at diagnosis
Passage *A* at birth	12	11 (2–4 months)
Passage *A* at birth, thymectomy and *Ak* thymus graft at 1 month	7	5 (3–5 months)
Passage *A* at birth, thymectomy and T_6 thymus graft at 1 month	8	1 (4 months)

Table 3. Immunogenetic and Cytological Analysis of Lymphoid Tumours arising in Thymus Grafts in Virus-inoculated Thymectomized $(AkXT_6)F_1$ Hosts

No. of mouse	Thymus graft	Transplantation results*			Cytological analysis		
		Growth in *Ak*	Growth in F_1	Growth in T_6	No. of *Ak* cells found	No. of F_1 cells found	No. of T_6 cells found
1	*Ak*	0/5	4/6	0/4	3	25	0
2	*Ak*	0/4	6/6	0/3	0	31	0
3	*Ak*	0/5	3/5	0/3	1	20	0
4	*Ak*	3/4	3/5	0/4	34	5	0
5	T_6	0/5	6/8	0/8	0	21	3
6	*Ak*	0/6	6/6	0/3	5	36	0

* Numerator, number of takes; denominator, number of animals.

The Question of a Thymus Hormone

Law[10] was the first to suggest that a non-cellular factor from the thymus might be exerting an influence in leukæmia development. In a series of experiments, as yet unconfirmed, Metcalf has given evidence for the existence of a lymphocytosis-stimulating factor from the thymus and suggested that this factor might be the non-cellular influence by which the thymus appears to determine leukæmogenesis[14]. In our laboratory, repeated injections of normal *Ak* thymus extracts have failed to restore the usual leukæmia incidence in thymectomized *Ak* mice. Non-cellular thymic extracts are thus probably not capable of replacing the thymus environment so far as leukæmogenesis is concerned.

The possibility of a humoral circulating factor from thymic transplants is suggested by the results obtained with intrasplenic thymus grafts. In contrast to subcutaneous grafts no lymphoid tumours arose from intrasplenic grafts in thymectomized irradiated mice[15], suggesting that a circulating leukæmic factor had been removed by the liver. In this laboratory, however, thymuses from intact day-old mice transplanted into the spleen of thymectomized virus-inoculated mice of the isogenic line have developed lymphocytic neoplasms, but the incidence of such tumours has been lower than that recorded for subcutaneous grafts in parallel experiments (Table 4).

Table 4. Development of Lymphocytic Neoplasms in Thymectomized *C3Hf/Gs* Mice bearing Intrasplenic Thymus Grafts

Inoculation at birth	Site of thymus graft*	No. of mice in group	No. of mice developing lymphoid tumours and age at diagnosis	Incidence (per cent)
Passage *A*	subcutaneous	26	20 (3–8 months)	77
Passage *A*	intrasplenic	38	17 (3–5 months)	45
Nil	intrasplenic	14	0	0

* Grafts were performed in all cases 6 days after thymectomy at 1 month of age.

Conclusions

It is apparent from the above series of experiments that the thymus does not influence leukæmogenesis by providing the source of a leukæmogenic virus nor the cells most susceptible to leukæmic transformation. It is doubtful whether it is required merely as a growth medium for the virus. It is known, however, that the thymus provides an environment wherein lymphocytes (whether produced in the thymus itself or by the rest of the lymphoid complex) can proliferate much more actively than in any other lymphoid tissue[16]. What determines this high local proliferative activity is unknown: it may be the non-cellular factor mentioned above or Metcalf's lymphocytosis-stimulating factor. It is possible, therefore, that neoplastic change occurs in virus-infected lymphocytes only if they proliferate at a rate characteristic of thymus lymphocytes. This suggestion could be put to experimental test, for example, by preventing virus-infected host lymphocytes from entering the thymus by isolating the latter in the anterior chamber of the eye or in a millipore diffusion chamber. Experiments of this type have been in progress for some time and their results will be published and discussed at a later date.

I am grateful to Prof. Alexander Haddow for his interest throughout this work. The investigations have been supported by grants to the Chester Beatty Research Institute (Institute of Cancer Research: Royal Cancer Hospital) from the Medical Research Council, the British Empire Cancer Campaign, the Jane Coffin Childs Memorial Fund for Medical Research, the Anna Fuller Fund, and the National Cancer Institute of the National Institutes of Health, U.S. Public Health Service.

EFFECTS OF HEAVY WATER ON POLIOVIRUS MULTIPLICATION: RESULTS AND SPECULATIONS ON MECHANISM

By Dr. DAVID KRITCHEVSKY, Dr. RICHARD I. CARP and Dr. HILARY KOPROWSKI
Wistar Institute of Anatomy and Biology, Philadelphia, Pennsylvania

THE multiplication of poliovirus (*MEF*-1 or *CHAT* strain) in cells previously grown in media containing deuterium oxide results in a five- to tenfold increase in burst size[1,2]. In these experiments, two stable tissue culture lines (HeLa and *MS*) and freshly explanted cells of rhesus monkey kidney were grown in concentrations of deuterium oxide, ranging between 20 and 40 per cent, prior to exposure to poliovirus. Incubation of these cultures at 37° C. resulted in increased virus multiplication in all the strains tested. When they were incubated at 40° C., virus strains which would not normally replicate at this temperature grew in the cultures. One example was the attenuated type 1 virus, the *CHAT* strain, which did not grow on monkey kidney cells at 40° C. in water medium, but replicated when the growth medium contained deuterium oxide or 50 per cent concentration in the overlay.

More recently, Lwoff and Lwoff[3,4] have described the effects of high concentrations of deuterium oxide on the multiplication of poliovirus I, rt. 38·5° at different temperatures, and have discussed possible mechanisms responsible for the results. In their experiments they added deuterium oxide (50 or 75 per cent) to a stable tissue culture line of human cancer cells, the *KB* line, immediately after infection with virus and found marked differences in virus yield as compared with water media in relation to the incubation temperature of the cultures. Thus at 33° C. there was a marked reduction in virus yield; at 37° C. more virus was produced; and considerably greater multiplication of virus occurred at 39·5°. Lower concentrations of deuterium oxide were apparently not tested, or had little or no effect.

Study of progeny of poliovirus grown in deuterium oxide at 40° *C.* The mutagenicity of deuterium oxide in certain bacterial and phage systems has been recorded[5–7] and the possibility that growth of poliovirus in deuterium oxide at elevated temperatures may give rise to mutants was investigated. The test system consisted of monkey kidney cell monolayers exposed to the attenuated *CHAT* or the virulent Mahoney strains of type I poliovirus and incubated at 37° and 40° C. respectively. One set of virus cultures was maintained at 37° C. throughout the experiment. A duplicate set was kept at 40° C. for 18 hr., then transferred to an incubator held at 37° C. Four days later the number of plaques appearing in all the plates were counted and ratios of those observed in cultures kept for a limited period at 40° C. to those observed in cultures kept consistently at 37° C. calculated. The results shown in the last column of Table 1 are expressed as differences between plaque ratios obtained for the test virus and standard *CHAT* virus.

The character of *CHAT* virus grown in deuterium oxide at 37° C. has not changed whereas different plaque ratios have been obtained for *CHAT* virus grown in deuterium oxide at 40° C. However, it should be emphasized that these ratios were obtained for virus grown in cultures kept at 40° C. for a limited time only (18 hr.). If cultures were kept at 40° C. during the entire incubation period no plaques of *CHAT* virus–deuterium progeny were detected. Since, however, growth of this progeny in cultures exposed to 40° C. for a limited time has also been observed following second tissue culture passage (without added deuterium oxide) it is felt that its character differs from that of the parental *CHAT* virus.

Table 1. Ability of Virus Strains to reproduce at 40° C.

Virus strain	No. of exps.	No. ratios determined	Ratio 40°/37° plaques*
Mahoney	9	9	+ 1·64 ± 0·36†
37°-D_2O-*CHAT*	7	8	− 0·02 ± 0·03
40°-D_2O-*CHAT*	7	12	+ 0·28 ± 0·03

* Ratio 40°/37° test virus—ratio 40°/37° *CHAT*.
† S.E.

Comparative effect of deuterium oxide and X-rays. Speculations concerning the mechanisms of action of deuterium oxide should take into account the fact[2,8] that tissue culture cells grown in deuterium oxide tend to become enlarged. Virus multiplication is increased in X-ray-produced giant cells[9], and it has been shown that the size of the irradiated cells is due to continued synthesis of large molecules in cells that have lost their ability to divide[10]. In preliminary experiments the *CHAT* strain of type I poliovirus[11] was grown on monkey kidney cell monolayers maintained in (*a*) normal growth medium, (*b*) in deuterium oxide and (*c*) irradiated by 300 r. Duplicate cultures were kept at 35° and 40° C. respectively. As judged by the average plaque size of the virus shown in Table 2, the effect of deuterium oxide seemed to be more pronounced than that of X-rays, but these conclusions may be revised after these cells have been subjected to different dosages of X-rays.

Table 2. Effects of Deuterium Oxide and of X-Irradiation (300 r.) on the Multiplication of *CHAT* Poliovirus on *MK* Cells at 35° C. and 40° C.

Medium	X-ray	D_2O (per cent)		Average plaque size 35° C.	No. of plaques per plate 40° C.
		Medium	Overlay		
H_2O	—	—	—	2·60	0
D_2O	—	40	—	2·63	0
H_2O	+	—	—	3·00	0·5
D_2O	—	—	50	3·14	4·0
D_2O	—	40	50	3·66	9·0

Speculations concerning mechanism of action of deuterium oxide. The mechanism by which deuterium oxide influences virus growth would appear to involve the extent of randomization of the virus structure and could manifest itself either by altering the stability of the hydrogen bonding in the molecule or by affecting the transition temperature of the helix-random coil transformation. Lwoff[12,13] has discussed the effects of temperature on virus multiplication.

Blout and Lenormant[14] have shown that the strong infra-red absorption bands of deoxyribonucleic acid (DNA) observed at 1,680 and 1,645 cm.$^{-1}$ are shifted to 1,660 and 1,625 cm.$^{-1}$ in deuterium oxide solution. The 1,660 and 1,625 bands are also observed with dry DNA and they conclude that this shift indicates stronger hydrogen bonding. A similar shift in the infra-red spectrum of RNA has now also been observed[15,16]. Thus the absorption which RNA normally displays in the 1,700–1,720 cm.$^{-1}$ region is shifted to 1,670–1,690 cm.$^{-1}$ in deuterium oxide solution. This absorption is thought to reflect base interaction (as between adenine and uracil) and to involve proton transfer.

Tne general effect of deuterium substitution on the strength of hydrogen bonds and on helix random coil transformations has been discussed by Scheraga[17]; and more recently it has been shown that differences in helix-coil transition temperatures depend on the specific chemical system under study being reduced by deuteration in poly-γ-benzyl-L-glutamate[18] and increased by deuteration in ribonuclease[19].

The deuterium effect, however, is most likely dependent on changes in the stability of the hydrogen bonding of the protein and possibly of the RNA. Interaction between the peptide bonds and the aqueous medium could affect the apparent half-life of a given virus particle; and increased stability of the hydrogen bond, such as could be conferred by deuteration, might then lengthen the effective half-life of the virus, resulting in increased multiplication.

Experiments now in progress may shed further light on the mechanism of the action of deuterium oxide.

MECHANISM OF MUTAGENESIS INDUCED BY FORMALDEHYDE

THE ESSENTIAL ROLE OF THE 6-AMINO GROUP OF ADENYLIC ACID (OR ADENOSINE) IN THE MEDIATION OF THE MUTAGENIC ACTIVITY OF FORMALDEHYDE

By Dr. THOMAS ALDERSON

Department of Genetics, University of Cambridge

In a previous communication[1], I have established by means of a chemically defined and axenic treatment medium that formaldehyde exhibits no mutagenic activity towards *Drosophila melanogaster* by the larval feeding method, unless adenylic acid is present in the treatment medium. A reaction-product formed between formaldehyde and adenylic acid in the treatment medium was postulated as the metabolite concerned in the mediation of the mutagenic activity of formaldehyde. The principal metabolite was assumed to be an adenylate dimer ($\overline{AA}$), where two adenylic acid molecules are linked together through their amino-groups by a methylene bridge. The stereochemical properties of this metabolite and its subsequent utilization in deoxyribonucleic acid synthesis, together with mechanisms for its mutagenic activity, were discussed[1].

An essential role was thus ascribed to the 6-amino group of adenylate for the formation of the adenylate dimer, since the binding of formaldehyde by ribonucleic acid mono- or poly-nucleotides appears to be a specific function of the amino-groups of their bases[2]. It is now found that adenylate is effective when present in the treatment medium as any of the forms adenosine-3′-phosphate, adenosine-5′-phosphate, or deoxyadenosine-5′-phosphate. The simple replacement of the 6-amino group of adenosine and adenosine-5′-phosphate by a hydroxyl group (to give inosine and inosine-5′-phosphate) completely removes the ability of these compounds to mediate the mutagenic activity of formaldehyde. Although adenosine is as effective as the adenine ribonucleotides, adenine shows no ability to mediate formaldehyde-induced mutagenesis and is actually anti-mutagenic on a formaldehyde-containing yeast–glucose treatment medium[3]. Adenine should be able to form a metabolite by reaction with formaldehyde similar to the one postulated for adenylate; but its free imino-group at the 9-position of the purine ring may be blocked by additional reaction with formaldehyde[4], thus preventing subsequent ribose sugar attachment; this condition would be expected to debar the utilization of adenine in nucleic acid synthesis.

The design of experiments[1,5], the method of treatment of larvæ[3], and brood pattern determinations of sex-linked recessive lethal mutation-rates[3] are as previously described. However, it has been found that a concentration of formaldehyde of

$1{\cdot}0 \times 10^{-2}\,M$, as against a previous concentration of $2{\cdot}0 \times 10^{-2}\,M$, results in an improvement in the mutational response and in the survival and development of the larvæ on the synthetic medium. This improved concentration was therefore used, as it more markedly illustrates the difference of effect of the various purine derivatives on the mutagenic activity of formaldehyde. Each nucleotide or nucleoside is used at a concentration of 0·1 per cent; adenine is used at an approximately equimolar concentration of 0·05 per cent. Ordinary medium is the oatmeal–treacle medium normally used for culturing *Drosophila* in this laboratory.

Table 1. EFFECT OF ADENOSINE, ADENOSINE-5′-PHOSPHATE, INOSINE AND INOSINE-5′-PHOSPHATE ON THE MUTAGENIC ACTIVITY OF FORMALDEHYDE WHEN NEWLY-HATCHED LARVAE ARE TREATED FOR 72 HR.

*r*A, adenosine; *r*H, inosine; *r*A5′-P, adenosine-5′-phosphate; *r*H5′-P, inosine-5′-phosphate.

Table 1 illustrates the results obtained when newly hatched larvæ are treated on the formaldehyde-containing synthetic treatment medium for 72 hr., and then transferred on to ordinary medium to complete their development. The presence of adenosine (*r*A) and adenosine-5′-phosphate (*r*A5′-P) in the treatment medium produces a high mutagenic activity of formaldehyde. However, if either inosine (hypoxanthine ribonucleoside, *r*H) or inosine-5-phosphate (hypoxanthine ribonucleotide, *r*H5′-P) is substituted for the corresponding adenine derivative, no induced mutagenic activity is detected. In comparing these two series of experiments, three differences should be noted. Thus, chemically, the only difference between the series is that the amino-group at the 6-position of the purine ring in adenosine and adenosine-5′-phosphate is replaced by a hydroxyl group in inosine and inosine-5′-phosphate. Biochemically, the adenine derivatives enter the organism with the correct purine groupings for utilization in nucleic acid synthesis, whereas inosine and inosine-5′-phosphate have first to be aminated before utilization in nucleic acid synthesis; since this amination takes place intracellularly a reaction-product of formaldehyde with these hypoxanthine derivatives in the treatment medium is therefore not formed. Biologically, the developmental response of *Drosophila* larvæ to the adenine and hypoxanthine derivatives is approximately equal; this suggests that they are utilized by the organism to approximately the same extent, and that the hypoxanthine derivatives are incorporated into the nucleic acids as adenylic acid, since this nucleotide component is the only one utilized to any appreciable extent. It has been shown[6] that when pyrimidines are excluded from the diet of developing *Drosophila melanogaster* larvæ, the development response to inosine is virtually the same as that of adenosine.

Table 2. EFFECT OF GUANOSINE-3′-PHOSPHATE, URIDINE-3′-PHOSPHATE, AND CYTIDINE-3′-PHOSPHATE ON THE MUTAGENIC ACTIVITY OF FORMALDEHYDE, WHEN NEWLY-HATCHED LARVÆ ARE TREATED FOR 72 HR.

*r*G3′-P, guanosine-3′-phosphate; *r*U3′-P, uridine-3′-phosphate; *r*C3′-P, cytidine-3′-phosphate.

It has been previously claimed[1] that the ribonucleoside-3′-phosphates of guanine, uracil and cytosine do not mediate the mutagenic activity of formaldehyde. Since the improved concentration for formaldehyde has been introduced, these compounds have been re-tested under the improved conditions; as seen in Table 2, the original findings were confirmed. In examination of the patterns of utilization of the ribonucleotide-3′-phosphates as growth requirements in *Drosophila melanogaster* larvæ, it has been shown[6] that the ribonucleoside-3′-phosphate of guanine, uracil and cytosine are not utilized when supplied in the absence of adenosine-3′-phosphate; consequently, metabolites formed by these compounds after reaction with formaldehyde would not be utilized in any event in this system. These compounds would therefore not be expected to mediate the mutagenic activity of formaldehyde.

Table 3 illustrates the results obtained when adenine (A), adenosine (*r*A), adenosine-3′-phosphate (*r*A3′-P), adenosine-5′-phosphate (*r*A5′-P), deoxyadenosine-5′-phosphate (*d*A5′-P), and inosine-5′-phosphate (*r*H5′-P) are tested for their ability to mediate the mutagenic activity of formaldehyde. For each treatment, the ribonucleoside-3′-phosphates

of guanine, uracil and cytosine are also added to the treatment medium, since an improvement in developmental time is found when these compounds are supplied as dietary supplements, though they are not otherwise concerned in the mediation of the mutagenic activity of formaldehyde (see Table 2). Adenine and inosine-5′-phosphate are seen not to be capable of mediating the mutagenic activity of formaldehyde, as expected from previous results with adenine[1] and inosine-5′-phosphate (Table 1). Adenosine, adenosine-3′-phosphate, adenosine-5′-phosphate, and deoxyadenosine-5′-phosphate are all found to mediate formaldehyde-induced mutagenesis ; but differences are observed in the mutagenic response produced by these adenine derivatives. Adenosine produces a significantly greater response in the first brood than adenosine-3′-phosphate and adenosine-5′-phosphate, whereas the response in the second brood is significantly greater with adenosine-5′-phosphate than with adenosine and adenosine-3′-phosphate. Second broods are usually sampled to detect any increase in the speed of germ-cell development, where such an effect may increase the mutagenic response in the second brood. Since the formaldehyde-containing medium loses its mutagenic activity after 24–48 hr., an increase in germ cell development may result in an increased number of cells passing into the sensitive stage of the second brood during the period of effective treatment. However, this does not appear to be the sole factor responsible here as the adenosine-5′-phosphate culture has a slower overall larval development-time than the adenosine, adenosine-3′-phosphate and inosine-5′-phosphate cultures. Deoxyadenosine-5′-phosphate shows a significantly lower ability to mediate formaldehyde-induced mutagenesis than the adenine ribonucleotides ; this may be because the concentration of deoxyadenosine-5′-phosphate used is not optimal for utilization by the larvæ. Data for the growth response of *Drosophila* larvæ to deoxyadenosine-5′-phosphate on the synthetic medium are not available.

As previously discussed[1], the mechanism of action of the postulated $\overline{AA}$ metabolite is mediated by way of deoxyribonucleic acid synthesis. However, the ribonucleotide derivatives of adenine (which are constituents of ribonucleic acid) are found to be more effective than the deoxyribonucleotide derivative (deoxyadenosine-5′-phosphate) tested, which is a constituent of deoxyribonucleic acid. Although relatively little is known of deoxyribonucleotide synthesis compared with that of ribonucleotide synthesis, it has been shown that ribonucleotides are effective deoxyribonucleic acid precursors[7].

It is thought that the synthesis of nucleotides follows a common pathway up to a point where a direct conversion of the ribo- to the deoxyribo-form takes place by simple enzymic reduction of the ribose sugar.

The nucleoside-5′-phosphates are the natural nucleotide precursors for ribonucleic acid, deoxyribonucleic acid, and nucleotide coenzyme synthesis. The ribonucleoside-3′-phosphates (which are products of alkaline hydrolysis of ribonucleic acid) are incorrectly phophorylated for direct utilization in these syntheses. In *Drosophila* larvæ the adenine ribonucleoside-3′- and 5′-phosphates are utilized, however ; but there is indirect evidence that dephosphorylation of these adenylic acids to adenosine precedes assimilation by the larvæ[6]. Thus, adenosine-5′-phosphate, adenosine-3′-phosphate, and probably deoxyadenosine-5′-phosphate would be converted to their nucleosides before assimilation. For reasons stated earlier, adenine, inosine, and inosine-5′-phosphate do not mediate the mutagenic activity of formaldehyde, although they are normally utilized by *Drosophila* larvæ. A schematic representation of these relationships is shown in Fig. 1.

IMPROBABILITY OF THE CHELATION HYPOTHESIS OF AUXIN ACTION

By Dr. D. D. PERRIN

Department of Medical Chemistry, Institute of Advanced Studies, Australian National University, Canberra

The suggestion has been advanced on biological grounds that plant-growth regulators exert their physiological effects through complex formation with certain cations, such as one or more of the heavy metals[1]. For example, with indole-3-acetic acid (IAA), chelation has been postulated to involve either the carboxyl group and the aromatic ring[2] or the imine and the carboxyl groups[1]. Because chemical evidence for any such mode of action has been scanty and conflicting, and no quantitative stability constant data for aqueous solutions have been published, the present definitive study was undertaken.

Cupric ion is the obvious choice for experiments aimed at providing such evidence because, of all the cations normally found in plant tissue, it forms by far the most stable series of complexes with all known ligands. Cohen *et al.*[2] found the absorption spectrum of IAA in 50 per cent aqueous ethanol was changed when copper nitrate was added: this they attributed to the formation of 1 : 1 and 1 : 2 copper complexes which, from *p*H titration data, had stability constants of $10^{3 \cdot 2}$ and $10^{5 \cdot 4}$. Recaldin and Heath[3], repeating this work, were not confident of the interpretation of the observed changes; in addition, they found the stability constant of the 1 : 2 complex to be $10^{3 \cdot 0}$, which is about 1/250 of the previous value. Afterwards, Fawcett[4] showed that in the experimental conditions a major contribution to the results came from hydrolysis of free cupric ion, a factor that had not been considered. Armarego *et al.*[5] failed to find any correlation between the growth activity of phenoxyacetic acids and the stability constants of their copper complexes.

All the foregoing results were obtained using 50 per cent ethanol solutions and hence should not be applied to interpret observations made on purely aqueous media, especially as complex formation between IAA and metal ions *in vitro* in water could not be demonstrated by either Cohen *et al.*[2] or Recaldin and Heath[3]. This failure was presumed to be due to the attainable concentrations of free IAA being too low. The poor solubility of IAA in water precludes the use of the Bjerrum *p*H-titration method of stability constant determination, which is based on the displacement of a proton from the free acid by the cation which forms the complex. A further complicating factor is the hydrolysis of cupric ion, which involves a polynuclear process[6] so that its extent varies with the copper concentration as well as with the *p*H, making it necessary to work either at low *p*H values or at low copper concentrations (or both). This limits the usefulness of spectrophotometric methods. However, the copper-amalgam electrode[7] can be made the basis of a sensitive method which is free of these defects and which has been used in the present instance. The potential of this electrode depends on the activity of cupric ion in the solution. If a high concentration of an inert supporting electrolyte, such as potassium nitrate, is also present, the activity coefficient of cupric ion remains constant so that when a complexing species is added to the solution the potential measures directly the free ion concentration. Knowing this quantity, as well as the total copper and ligand concentrations, enables the stability constant of the complex to be calculated.

Experimental conditions (solution about *p*H 5 and initial copper concentration of 5×10^{-4} *M*) were chosen so that hydrolysis of copper ion was negligible[6], while, at the same time, advantage could be taken of the much greater solubility of the anions of the acids tested. The self-buffered solutions of IAA and α-naphthylacetic acids that were added were 1 *M* in potassium nitrate and 0·025 *M* in the acid plus its potassium salt; for the other acids a concentration of 0·05 *M* was used. Even at these concentrations, which in some cases represented supersaturated solutions, only very small changes in potential were observed and great care was needed for their measurement against a saturated calomel electrode. For this reason a potentiometer (Tinsley vernier) and galvanometer (Cambridge spot) combination was selected which could be read easily to 0·02 mV., and a Vibron electrometer *p*H meter with attached recorder was used to provide a continuous check on the *p*H of the solutions. The copper–amalgam surface was freshly exposed and solutions were kept at 20·0° C. in an atmosphere of nitrogen.

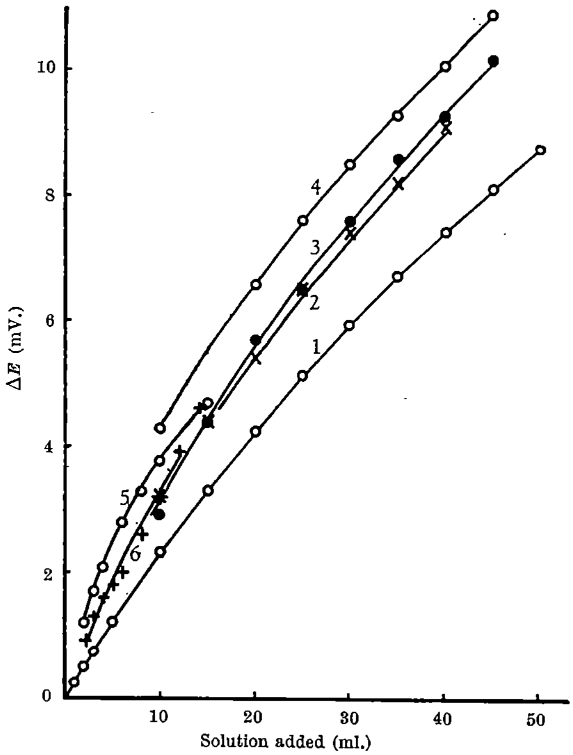

Fig. 1. Change in copper–amalgam electrode potential at *p*H 5·0 when 50 ml. 5×10^{-4} *M* copper nitrate in 1 *M* potassium nitrate was diluted with: (1) 1 *M* potassium nitrate; (2) 0·05 *M* 2,4-dichlorophenoxyacetic acid buffer; (3) 0·05 *M* 2,4-dimethylphenoxyacetic acid buffer; (4) 0·05 *M* 4-chlorophenoxyacetic acid buffer; (5) 0·025 *M* indole-3-acetic acid buffer; (6) 0·025 *M* α-naphthylacetic acid buffer. Solutions 2–6 were also 1 *M* in potassium nitrate

From the small but reproducible differences shown in Fig. 1 the stability constant, $K_1 = (\text{Cu}.L^+)/(\text{Cu}^{++})(L^-)$, where (L^-) is the anion concentration of the complexing species, has been calculated for the 1 : 1 complexes of each of the acids tested. The results set out in Table 1 show log K_1 to range from 0·8 to 1·7. This indicates that no greater degree of complex formation occurs than is known to exist in the cupric salts of simple carboxylic acids such as acetic and chloroacetic[8]. The slight increase of log K_1 values with the pK_a of the acids reflects only the commonly observed general parallelism between the strengths of binding of metal ions and protons in any related series of ligands. No evidence was obtained for the formation of 1 : 2, or higher, complexes, in agreement with the usual observation for many acids that log K_2 of their complexes is much less than log K_1.

The stability constants of the copper complexes of IAA and acetic acid are almost identical and, as the pK_a values of the two acids are comparable, the conclusion is inevitable that in IAA, also, only the carboxyl group plays any part in complex formation. For this reason, it appears justifiable to take the stability constants of complexes of other metals with IAA to be the same as for the corresponding acetates[9]. For zinc-, calcium- and magnesium-IAA complexes the constants would be about 1/10, 1/40 and 1/40, relative to copper.

Although the present results show the plant-growth acids of the types investigated to be only weak complexing agents, it is of some interest to assess the maximum possible extent to which they might form

Table 1. Ionization Constants of Some Plant-Growth Regulators and the Stability Constants of their Copper Complexes

Acid	pK ($\mu=0{\cdot}0005$)	$pK_{\text{conc.}}$ ($\mu=1$, KNO_3)	$\log K_1$ (copper complex)
2,4-Dichlorophenoxyacetic	2·90	2·78	0·8
4-Chlorophenoxyacetic	3·00	2·91	1·1
2,4-Dimethylphenoxyacetic	3·22	3·08	0·9
α-Naphthylacetic	4·22	4·04	1·4
Indole-3-acetic	4·54	4·36	1·7
Chloroacetic (ref. 8) (for comparison)		2·66	0·91
Acetic (ref. 8) (for comparison)		4·61	1·65

metal complexes under biological conditions, taking for this purpose the ions Cu^{++} and Zn^{++}. Based on figures for metal–acetic acid complexes[9], the reasonable assumption is made that changing the ionic strength of solutions of 1·0–0·15 only slightly increases $\log K_1$.

The total copper concentration in fresh plant tissue does not often exceed 1 p.p.m., that is, 17 μM. Young and growing tissue contains a higher free amino-acid concentration than mature tissues[10,11], but, even in the latter, total free amino-acid concentrations in excess of 5×10^{-3} M have been found in normal bracken, spinach beet and pea leaves[11]. It can readily be calculated from the latter figure (using 9·5 as the average pK of amino-acids, and 8·5 and 15·5 as the average log stability constants of their 1 : 1 and 1 : 2 amino-acid complexes at 20° (ref. 9)) that at pH 7 the free cupric ion concentration in plant tissues must be less than 10^{-11} M. Even then, this figure takes no account of the presence of competing ligands such as proteins, which must reduce the free copper concentration even further. Growth-stimulation has been demonstrated at concentrations of 10^{-9} M IAA[1], which, from the above results, must represent a copper–IAA complex concentration of less than 10^{-18} M. For similar calculations with zinc, an average zinc content of 3 mgm./kgm. green tissue has been taken. (This is an arbitrary figure because the zinc content of plants varies considerably with differences in soil zinc-level, but, from a summary of the literature[12], 1–10 p.p.m. seems to be the normal range). Taking an average log stability constant of 5·3 for 1 : 1 zinc–amino-acid complexes[9] leads to the conclusion that the concentration of zinc–IAA complex in plants must be less than 10^{-14} M. Both this and the copper value are so very much less than for any known biologically active substances as to make it extremely probable that metal-complex formation plays no part in the physiological activities of IAA and the other plant-growth regulators discussed above.

I thank Prof. R. L. Wain, of Wye College, University of London, for outlining the biological problem, and, together with Dr. S. F. Cox, of Imperial Chemical Industries, Ltd. (Australia and New Zealand), Melbourne, for kindly supplying the acids used in this work. I am grateful to Prof. A. Albert for helpful discussion.

ENVIRONMENTAL FACTORS AND BRYOPHYTES

By KATHRYN BENSON-EVANS

Department of Botany, University College of South Wales and Monmouthshire, Cardiff

MOST plants appear to show a definite rhythm or periodicity in their vegetative growth, and to a more marked extent in their reproduction, connected with a periodicity in some factor or factors of their environment.

As early as 1925, Wann[1] suggested that all plants (with the possible exclusion of fungi and lichens) can be grouped into 'long-day' and 'short-day' plants depending on the photo-period or length of daily illumination which results in the production of 'flowers' and 'fruit'. Since then, the responses of higher plants to photo-periods, temperature, and auxins or growth substances and the interactions of these factors have been increasingly investigated. Relatively little, however, has been accomplished in the field of mosses and liverworts, probably because of the slight economic importance of these plants.

This article aims at reviewing some of the preliminary experimental work which has been performed with these groups, with particular reference to the environmental factors that influence vegetative growth and induce the sexual or sporangial condition.

Wann initiated work in this field by carrying out photo-periodic experiments using *Marchantia polymorpha* as his material, and his results indicated that *Marchantia* appeared to respond to photo-periods as do long-day plants in the higher plants. Voth and Hamner[2] repeated these experiments under improved conditions and again demonstrated certain definite photo-periodic responses in both vegetative thalli and sex organs, in both long- and short-day conditions, irrespective of the nutrient supply: (*a*) plants under long-day conditions were always larger and had greater dry weight than plants on comparable solutions under short-day conditions; (*b*) plants under long-day conditions produced a greater number of gametangiophores than similar plants on comparable solutions under short-day; (*c*) plants under short-day conditions produced a greater total number of gemmæ cups than plants on comparable solutions under long-days; (*d*) it was also noted that low humidity retarded the responses especially of the female branches and organs, whereas high humidity hastened the response.

Similar experiments were carried out at Cardiff using three other genera of the Marchantiales. In view of the results of Voth and Hamner, no attempt was made to culture plants on specific media, but turfs growing on their natural substrate were collected from the field. The experimental chambers were illuminated by six 4-ft., 40-W. fluorescent tubes supplemented by two red fluorescent tubes to make up the deficiency in waves from the red end of the spectrum. Heating was performed with a diffused heating spiral, and temperature was controlled by a cartridge thermostat to within ± 1° F. Intensity of light was about 800–1,000 ft.-candles at a distance of 1 ft. from the light source and measured at the surface of the plants. Day-length was controlled by Venner time switches. A second series of cabinets showed a greater fluctuation of temperature as they were not heated independently.

In all the species investigated, increased vegetative growth occurred in the long-day chambers, and sexual branches were stimulated on these plants; the plants under short-day conditions remained vegetative (Table 1).

Table 1

Species	Long-day				Short-day			
	Plants used		Plants responding		Plants used		Plants responding	
	♂	♀	♂	♀	♂	♀	♂	♀
Marchantia polymorpha	62	91	35	58	51	56	0	3
Preissia quadrata	62	177	41	141	40	72	0	0
Conocephalum conicum	94	119	88	89	52	61	0	0
Lunularia cruciata	85*	103	47*	86	38	67	0	2

* Denotes field observations (August).

Average maximum temperature, 65° F.; average minimum temperature, 46° F.

The response of *Marchantia polymorpha* to increased light intensity was checked. It was found that plants in experimental chambers having supplementary lighting always responded more rapidly than those in a lower light intensity, but that day-length influenced the actual number of gametangiophores that were produced (Table 2). This would appear to be comparable with the reactions of higher plants, since Mann[3] demonstrated a similar effect on floral initiation in *Xanthium*, where increase in light intensity increased the effect of the photo-period.

Table 2. PHOTO-PERIODIC AND LIGHT INTENSITY EFFECTS IN THE MARCHANTIALES

No. of gametangiophores produced in response to differing light intensities

Period of response (weeks)	14 hr. (500 ft.-candles)	14 hr. (1,000 ft.-candles)	18 hr. (1,000 ft.-candles)
1	0	0	0
2	0	3	30
3	0	7	35
4	2	7	35

Average maximum temperature, 76° F.; average minimum temperature, 58° F.

The response of *Lunularia cruciata* was of particular interest, since sexual reproduction in this form only occurs sporadically in the British Isles and in many other countries.

Experimentally, archegoniophores were only induced to develop during the months of December to March inclusive, when plants from the field, transferred to a temperature of 70° F. and long-day conditions, would produce archegoniophores within 7–8 days[4]. A temperature as low as 60° F. has been found to be just as effective early in the year and, owing to the rapidity with which *Lunularia* can produce sexual organs, the temperature stimuli need only be maintained for a few days. Later collections, that is, after March, remained vigorously vegetative, so that apparently there may be a low-temperature requirement which must be fulfilled before the stimulus of a rise in temperature. Other evidence of this is shown by plants grown from gemmæ, for these do not produce archegoniophores until the following spring, having first passed through the cold period of winter. Plants suffering from frost damage do not produce sexual branches; their apices give vegetative growth throughout the following season. Only plants kept at low temperatures, but protected from frosts, give rise to branches with reproductive organs when submitted to a rise in temperature and long days. Male branches have not been stimulated experimentally, but field records suggest that a summer temperature of 70–80° F. is necessary for their initiation.

Lunularia contrasts strongly with *Conocephalum conicum*, a native of Britain, which dies back in winter and regenerates from the apex each spring. It has been found that when dormant clones of *Conocephalum conicum* are transferred to growth chambers at 70° F. and long days, vigorous vegetative growth occurs, but after 2 weeks the apices begin to produce sexual branches. Clearly in *Conocephalum*, the death of the older parts of the thallus does not affect the ability of the regenerated branches to produce sexual organs.

Temperature apparently did not affect the response in this species or in *Preissia quadrata*, where the stimulus of long days is wholly responsible for the re-orientation of the growth of the thallus from the horizontal to the vertical plane, which is the first step to the production of the sexual receptacles. It would appear that this re-orientation is probably correlated with the synthesis of growth hormones, or the removal of a growth inhibitor, in the long days, since Rousseau[5] apparently demonstrated that the external application of auxins (2,4-dichlorophenoxyacetic acid, α-naphthalene-acetic acid, and β-naphthoxyacetic acid) to the vegetative plants of *Marchantia polymorpha* induced morphology comparable to the receptacles of normal plants. I have also induced a similar re-orientation of the thallus with receptacle formation in *Conocephalum conicum* using 2,4-dichlorophenoxyacetic acid, at a concentration of 10^{-4}, but no sex organs were formed. Other experiments indicated that application of high auxin concentrations to the normal young receptacles of these species in early summer inhibited the formation of sex organs. These observations are of interest in view of the work of Salisbury[6], who, among others, has demonstrated that the flowering of many higher plants is influenced by the application of auxin. High concentrations were inhibitory to the flowering, not only of short-day plants, but also of many species including long-day and indeterminate forms.

Normally the female receptacles remain very shortly stalked until fertilization has occurred. In *Conocephalum conicum* this occurs in the field in June, and the sporogonia develop soon after, but the stalk of the archegoniophore does not elongate until the following spring, usually from March onwards into the summer. Elongation of the stalk occurs by extension of the individual cells comprising the stalk and not by cell division.

Table 3. EFFECT OF VARYING CONCENTRATIONS OF 2,4-DICHLOROPHENOXYACETIC ACID ON THE ARCHEGONIOPHORE STALKS OF *Conocephalum conicum*

Days after treatment	Concentration of 2,4-D					
	10^{-3}	10^{-4}	10^{-5}	10^{-6}	10^{-7}	Control
	Average length of archegoniophore stalks in mm.					
7	2·0	1·5	2·0	2·0	1·5	2·0
14	5·0	11·0	11·0	4·0	2·0	2·0
21	5·0	11·0	11·0	12·0	2·0	2·0
28	5·0	11·0	11·0	18·5	2·0	2·0

Average maximum temperature, 62° F.; average minimum temperature, 58° F. Normal day-length for October–November.

We have[7] stimulated elongation in the archegoniophore stalks of *Conocephalum conicum* in October, by the external application of 2,4-dichlorophenoxyacetic acid, greatest elongation occurring at a concentration of 10^{-6} (Table 3). This suggests that normal elongation is brought about by a natural auxin produced within the gametophyte. As normal elongation occurs in the spring, the production of auxin may be stimulated by the greater temperature and photo-period of the spring days. To ascertain whether increased photo-period alone would stimulate endogenous auxin production, and thus bring about elongation, portions of the female thallus bearing archegoniophores were subjected to long-day conditions (16 hr.) at normal winter temperatures (January). No elongation occurred and so it was assumed that photo-period alone was not sufficient to stimulate auxin production, or at least in sufficient quantity to bring about elongation of the cells. A second group of plants was subjected to long-day treatment in a heated greenhouse at an average temperature of 60° F., when elongation of the stalks occurred (Table 4). Higher temperatures had a retarding effect, as did short days at both temperatures, indicating that the long photo-period combined with a temperature of 60° F. was optimal for cell elongation. This appears to be an effect similar to that observed by Knott[8], when studying the effect of temperature on the photo-periodic response of spinach. With the photo-period fixed at 15 hr./day, seed stalk elongation occurred sooner if temperatures during treatment were held at 60–70° F. than it did if held at a higher or lower range.

Table 4. EFFECT OF PHOTO-PERIOD AND TEMPERATURE ON ELONGATION OF THE ARCHEGONIOPHORE STALK OF *Conocephalum conicum*
Responses given for 5 archegoniophores after 4 weeks

Temperature		16 hr.		8 hr.	
Maximum	Minimum	Average length	No. responding	Average length	No. responding
40° F.	34° F.	2·0 mm.	0	1·5 mm.	0
62° F.	58° F.	19·0 mm.	5	1·5 mm.	0

That a natural auxin is present in the thalli has been demonstrated by Dickson[9], and Larue and Narayanaswami[10], who obtained positive results with *Avena* tests of the extracts of thallus tips of *Lunularia* and *Marchantia*. Preliminary experiments with analysis of such extracts by paper chromatography suggest that the auxin involved may be indole-3-acetic acid.

The sporophytes of the Marchantiales are small and more or less parasitic on the gametophyte, although some chlorophyll is formed. Hughes[11] has shown that in *Conocephalum conicum* sporophytes are complete in all their organs, 8 weeks after fertilization, but the slight elongation of the seta, typical of liverworts, had not occurred. With the temperature maintained at 70° F., half the plants were placed in long-day, and half in short-day, conditions. The development of the sporophytes was not found to be influenced by day-length.

Seta elongation has been induced by external application of auxin to young sporophytes of *Conocephalum conicum* in early autumn. This elongation was not influenced in any way by differences in day-length, and although capsules dehisced normally the spores were not viable.

Of the seven species so far investigated in the Jungermanniales, six appear to react as long-day plants, the sexual organs being stimulated to form in December and January, on plants placed in experimental chambers in long days, with a maximum temperature of 65° F. and a minimum of 46° F. Plants in short days remained vegetative at similar temperatures (Table 5).

Table 5. PHOTO-PERIODIC RESPONSES IN THE GAMETOPHYTE OF SOME JUNGERMANNIALS

Material	16 hr.		8 hr.	
	Plants used	Plants responding	Plants used	Plants responding
Diœcious forms	♂ ♀	♂ ♀	♂ ♀	♂ ♀
Riccardia pinguis	28 70	11 34	14 29	0 0
Cryptothallus mirabilis	5 10	3 9	5 10	2 7
Diplophyllum albicans	157	66 38	184	0 0
Monœcious forms				
Riccardia multifida	79	52	67	0
Pellia epiphylla	76	44	82	0
Lophocolea cuspidata	124	83	137	0
Lophocolea heterophylla	115	78	121	0

Average maximum temperature, 65° F.; average minimum temperature, 46° F., December–January.

Of interest in this group is the behaviour of *Cryptothallus mirabilis*. In Nature, the plants are found up to approximately 3 in. below the surface of leaf litter or a moss carpet overlying peat or humus. The thallus is often heavily infected with fungal hyphæ, which destroy the chlorophyll in many of the cells. The apices of young branches from which the sex organs arise are usually free from fungus. In this form the sexual organs are not produced in response to a particular day-length, but to a rise in temperature.

Experimentally, the organs formed in both long- and short-day conditions within 5 weeks of the plants being transferred from the field to the higher temperatures of the experimental chambers. Plants kept continuously in a warm greenhouse at 65° F. remained vegetative throughout the winter and the following season, suggesting that here, as in *Lunularia*, there may be a low-temperature requirement that must be fulfilled before the stimulation of a rise in temperature.

As in Marchantiales, maturation of the sporophytes is independent of day-length, but Crombie and Paton[12] have demonstrated that temperature affects seta elongation. They have shown that older sporophytes of *Pellia epiphylla*, left in the field until January or February, respond more rapidly to a temperature stimulus in the laboratory than do sporophytes collected in early autumn. They suggest that during the winter there is a slow synthesis of growth hormones (or removal of a growth inhibitor), which is stimulated to some extent by temperature and extra light. That temperature may well be the more important factor is indicated by the results of the experiments I have carried out in November on plants kept at an average temperature of 60° F. Application of various concentrations of 2,4-dichlorophenoxyacetic acid to plants bearing young sporophytes caused seta elongation to occur in the three liverworts investigated, maximum extension occurring at a concentration of 10^{-6} (Table 6). A study of seta elongation by time-lapse photography has also indicated that the extension of individual setæ of these genera often occurs over a period of two or three days, and that there is a period of growth immediately following sunset each day (Fig. 1). It is realized that growth could have been influenced by the light flashes used for the photographs, but if this light source were significant, one would have expected a more marked effect on the growth curves obtained.

Table 6. EFFECT OF VARYING CONCENTRATIONS OF 2,4-DICHLOROPHENOXYACETIC ACID (2,4-D) ON SETA ELONGATION IN SOME JUNGERMANNIALES

Species	Concentration of 2,4-D					
	10^{-3}	10^{-4}	10^{-5}	10^{-6}	10^{-7}	Control
	Average length of setæ in mm.					
Pellia epiphylla	5·0	13·8	14·5	28·5	24·0	1·0
Cryptothallus mirabilis	1·0	4·0	16·0	18·6	17·2	1·0
Lophocolea cuspidata	0·5	0·5	12·5	22·5	21·0	0·5

Results after 14 days.
Average maximum temperature, 60° F.; average minimum temperature, 58° F., November–December.

Experiments by Asprey *et al.*[13] also have shown that external application of indole-3-acetic acid can produce seta elongation in young sporophytes of *Pellia*, and that addition of gibberellin gives greater extension than with the auxin alone—an average of 63 mm. in length as compared with 37 mm. in the former case.

Brian and Hemming[14] have presented evidence that gibberellin often depends on the presence of indole-3-acetic acid for its activity. Brian[15] suggests that gibberellin is produced naturally in plants in response to light, vegetative growth being proportional to the amounts of gibberellin and indole auxins which are formed. He suggests that this may well be true of the extension of *Pellia* setæ, and that gibberellins formed during daylight are utilized in the dark period.

Hughes carried out experiments on *Anthoceros laevis* in April and May when plants from the field had already discharged their antheridia and young sporophytes were formed on the dorsal surface of the thalli of the female plants.

Plants were placed in experimental chambers under long- and short-day conditions at temperatures of 70° F. and 50° F. in each case. After a month, the male plants were sexually fertile in short days at both temperatures, the antheridia developing on new lobes of the thalli. Plants under long-day conditions remained sterile. Subsequent experiments have shown similar results for the female plants (Table 7).

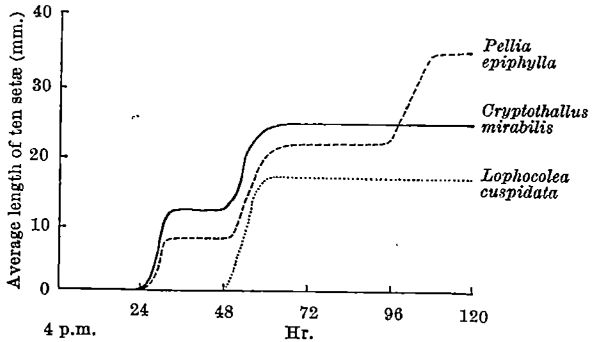

Fig. 1. Rate of seta elongation in three liverworts, based on time-lapse photographs 55° F.; hr. of darkness, 5.30 p.m.–8.0 a.m.

Table 7

Anthoceros laevis	18 hr.		6 hr.	
	70° F.	50° F.	70° F.	50° F.
Male plants	vegetative	vegetative	fertile	fertile
Female plants	vegetative	vegetative	fertile	fertile
Sporophytes	rapid vegetative growth	slow vegetative growth	slow vegetative growth	slow vegetative growth

When investigating the responses of the sporophytes, Hughes was able to show that after 8 weeks those sporophytes which had been maintained under long-day conditions exhibited almost unlimited power of vegetative growth due to the basal meristem, as compared with the low vegetative growth in short days. There was no difference, however, in the rate of spore production in long and short days. It was concluded that development of the sporophyte in this species is not induced by the photo-period except for a difference in the rate of the two sporophytes vegetatively. The length of the photo-period did not affect the embryonic tissue.

In the Sphagnales, as yet, I have made only a few preliminary observations on *Sphagnum plumulosum*. Material collected in August and kept in a glasshouse in short-day conditions produced sex organs in December. The male branches changed colour as they matured and appeared as red catkins in early February when the antheridia dehisced. Dissection of the apices of branches of the female plants showed that archegonia were present. Plants in experimental chambers under long-day conditions did not produce sex organs (Table 8).

Table 8

Material	16 hr.				8 hr.			
	Plants used		Plants responding		Plants used		Plants responding	
	♂	♀	♂	♀	♂	♀	♂	♀
Sphagnum plumulosum	134	115	0	0	110	107	54	31

Average maximum temperature, 76° F.; Average minimum temperature, 58° F.

In the field, plants were producing sex organs in late February and early March, capsules had formed by May, but these did not mature and dehisce until July. As yet there is no experimental data concerning the effect of temperature or day-length on the maturation of the sporophyte. The only record of auxin action in this group is the work by Patterson[16], who demonstrated that nearly mature capsules with unelongated pseudopodia gave maximum extension within 3–4 days when moistened with indole-3-acetic acid at a concentration of 10^{-6}. Higher concentrations of auxins, however, inhibited or entirely prevented elongation, a reaction similar to that recorded for the receptacles and stalks of the Marchantiales.

There is therefore some evidence that *Sphagnum plumulosum* may well be a short-day plant, but more confirmation is required.

Of the Bryales or true mosses, the only experimental work so far has been carried out by Hughes using *Polytrichum aloides* and *P. piliferum*.

In *Polytrichum aloides* mature sex organs are produced in the field from March until May, but arche-

Handbook of Organometallic Compounds

HERBERT C. KAUFMAN, John B. Pierce Foundation.

This handbook brings together all the known data on organometallic compounds that have been reported in the literature. For the individual compound, it gives the formula, name, molecular weight, state of aggregation, solubility, refractive index, density, vapour pressure, and all the other physical, chemical and thermodynamic properties which are available. The compounds are grouped in chapters according to the metal or other element which constitutes the central atom; and each is arranged essentially in order of increasing carbon content, followed by the non-carbon compounds. In addition to its broad appeal to chemists, this book should prove indispensable to the plastics industry, and to all those working on fuel and propulsion problems in the aircraft and missile fields.

6¼ × 9½, 1,400 pp., July 20th, 169s.

Rare Earth Alloys

KARL GSCHNEIDNER, Jr., University of California, Los Alamos Scientific Laboratory; consultant, Atomic Energy Commission.

This review of the rare earth alloy systems presents such information as phase diagrams, crystallographic and thermodynamic data, and physical and mechanical properties concerning these alloys assembled into a single, critical compilation. It should benefit those primarily engaged in research in the field of metals, and also those specializing in solid state physics, i.e. investigating intermetallic compounds.

145 illus., 6 × 9, 500 pp., July 20th, 96s.

Introductory Chemistry 2nd Edition

OTTO W. NITZ, Professor of Science and Mathematics, Stout State College, Wisconsin.

The second edition presents an exceptionally clear discussion of chemical principles and of the common elements and their compounds. The theoretical base of chemistry has been strengthened in this new edition, and the order of presentation has been provided where experience indicated their need. Coverage of the section on biochemistry has been widened, and the chapter on organic chemistry is now reorganized and extended. Sections on historical background and industrial methods have been revised and, in some instances, enlarged. There are some 40 new illustrations.

266 illus., 6 × 9, 600 pp., July 20th, 60s.

Linear Differential Operators

C. LANCZOS, Senior Professor, School of Theoretical Physics, Dublin Institute for Advanced Studies.

This book deals thoroughly with certain new and advanced topics in mathematical analysis, and is likely to interest engineers, mathematical physicists and other applied mathematicians. By examining the properties of certain mathematical entities, notably the Green's function, Professor Lanczos conducts a broad investigation into linear differential operators, taking as his central theme the identity of form and treatment between these operators and matrix algebra. Though the primary emphasis is on the analytical theory, concrete cases are cited to forge the link between theory and practice.

6 × 9, 580 pp., 58 diagrams, 3 tables, August 24th, 80s.

International Dictionary of Physics and Electronics 2nd Edition

The new revised and enlarged second edition of this famous dictionary, complete with multilingual indices in Russian, German, French and Spanish, is now published.

For a limited period (until August 30th, 1961) it is offered to the public at the specially reduced price of £9 5s. od. Thereafter it will be £10 5s. od. A leaflet giving further details may be obtained on request from the publishers.

Immunochemical Approaches to Problems in Microbiology

Edited by MICHAEL HEIDELBERGER and OTTO J. PLESCIA,
Institute of Microbiology, Rutgers, The State University

A volume based on a recent Symposium designed to bring together scientists representing different disciplines to consider more effective utilization of immunochemical methods in the further development of microbiology.

The scientific papers and discussion by panelists and invited audience cover the following topics: Quantitative immunochemical aspects of microbial specificity: precipitation and inhibition techniques, multiplicity and specificity of bacterial antigens, immunochemistry of viruses, so-called non-specific factors in immunity, and biosynthesis of antigens and antibodies.

The panelists were Ö. Ouchterlony, Pierre Grabar, H. G. Kunkel, J. H. Rockey, T. Tomasi, J. R. Marrack, Paul H. Maurer, E. A. Kabat, J. Baddiley, Maclyn McCarty, James T. Park, D. L. Shrivastava, C. A. Knight, Lawrence Levine, Igor Tamm, Purnell W. Choppin, Becca Patras, Fred Karush, Raymond Latarjet, G. Biozzi, O. G. Bier, Elmer L. Becker, Otto J. Plescia, Manfred M. Mayer, Irwin H. Lepow, Robert A. Nelson, Jr., Myron A. Leon, Evelyn E. B. Smith, George T. Mills, Robert Austrian, Harriet P. Bernheimer, Brigitte A. Askonas, Felix Haurowitz, Maxwell Richter, G. J. V. Nossal, and O. Mäkelä.

402 pages with illustrations and index. £2 3s

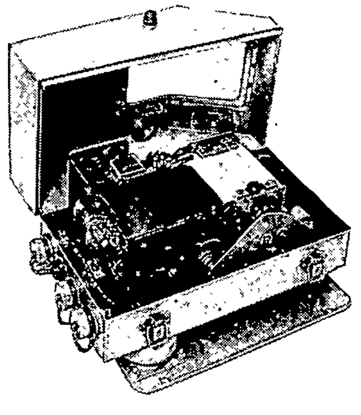
Hendrey Spark Recorder Type 1487A



For full details and specification ask for Catalogue Sheet A4

Compact and weatherproof, this single channel recorder is light in weight and easily portable. The Perspex window gives a clear view of the heat-sensitive chart for approximately 6 in. of its length.

The instrument can also be used mounted on bench, wall or panel and is supplied with mounting plate incorporating three anti-vibration mountings which render the instrument shock-proof and vibration-proof to service standards.

An electro-magnetically operated stylus, operated by a separate switch not supplied with the recorder, provides transverse markings near the edge of the chart. Provision is made for an external alarm circuit which can be pre-set to operate at any deflection from zero to full scale by means of a control on the case.

Sensitivity—50 micro-amps. Full scale. Supply—12 Volt, D.C.

TRANSIENT IMAGE BECOMES PERMANENT RECORD

with the new S & P direct-writing

OSCILLOGRAPH RECORDER

A highly-advanced and versatile unit with the important advantages of very high speed and sensitivity. Special pencil-type mirror galvanometers trace records on 6-in wide ultra-violet sensitive paper which requires no processing.

PERFORMANCE DETAILS

Permanent continuous or intermittent records can be made at frequencies from d.c. to frequencies in excess of 1,000 c.p.s. The system gives a well defined trace, at writing speeds above 12,000 in. per sec. Choice of 8 paper speeds, from 5 in. per min. to 150 in. per sec. 12 channels, but with 3 additional channels for time, event, datum reference lines, or for use as additional signal channels if desired. Matched amplifiers and power supply units can be supplied.

APPLICATIONS

Industrial, Scientific, Medical and Military . . . Because a transient tube image is replaced by permanent records for analysis, this unit will have special value for many purposes in universities and technical colleges. Other applications include: Stress analysis by electrical strain gauge techniques. Testing heavy electrical equipment. Records of electric power supply characteristics. Laboratory process analysis. Missile and gun performance testing, and general telemetery use. Cardio-vascular and respiratory investigation.

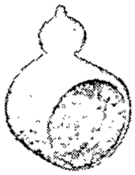
SCINTILLATION COUNTING

Precision Nucleonic Instruments (Bulletins 14, 15, 16, 18, 19, 20, 21, 22, 24)
The Human Body Monitor shown above forms one of a series completed for Atomic Energy Establishments and hospitals in Britain, Canada, Germany and Australia by Nuclear Enterprises Low Level Division. Standard instruments and assemblies include non-overloading linear pulse amplifier NE 5202, pulse height selector NE 5103, EHT supplies, ratemeters, NE 8301 assembly for H3 and C14 counting and scanning scintillation spectrometer NE 8601.

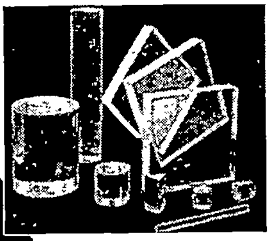
Spiral Flow Cell: For beta emitters in liquids and gases. Used for flow studies in biology and medicine, it gives 10% and 60% efficiencies for C14 (liquid and gas respectively).

Neutron Detectors: Boron polyester systems, greatly improved Hornyak systems, and highly directional fast neutron detectors.

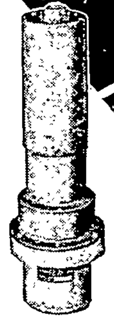


Liquid Scintillators & Scintillation Chemicals: Liquid and loaded liquid scintillators (lead, tin, cadmium, gadolinium, boron, etc.), terphenyl, POPOP, P.P.O., BBO, T.P.B., DPA, hyamine, dioxane, etc.

Crystal Scintillators: Wide range and high resolution NaI(Tl), CsI(Tl), and LiI(Eu) mounted scintillation crystals. Thicknesses down to 0·002″ and diameters up to 9″.



Plastic Scintillator NE 102: Available in complete range of rod, sheet, filament, well, sphere and tube form. Light output 65% anthracene, decay time 3·5 millimicroseconds. Linear dimensions from 1 micron to 1 metre.



Crystal-Photomultiplier Assemblies: Scintillation crystal head units offering improved resolution. NaI(Tl), CsI(Tl) and LiI(Eu) in integral and demountable assemblies with crystal sizes up to 9″ diameter.

SCINTILLATORS

The unique scintillation service afforded by Nuclear Enterprises (G.B.) Ltd. includes the highly efficient NE 102 plastic scintillator, liquid scintillators, neutron detectors, scintillation chemicals and an extensive range of crystals & crystal-photomultiplier assemblies.

New:

NE 150 plastic phosphor for pulse shape discrimination techniques and NE 160 a special high temperature plastic scintillator.

MANUFACTURERS OF ELECTRICAL EQUIPMENT INCLUDING RADIO AND TELEVISION COMPONENTS

. . . . built for a lifetime of constant use

The 'SERVICE'

The "Service" is without doubt the finest student microscope today and has proved its high quality and serviceability in many school and university laboratories throughout the world. The simplicity of its design is allied with the highest standards of construction, resulting in a high quality instrument easy to work with and capable of giving a lifetime of satisfactory service in constant use. The comprehensive range of accessories, designed to make the "Service" suitable for more complex work is of equally high quality. See the Watson "Service" before you decide on your next microscope.

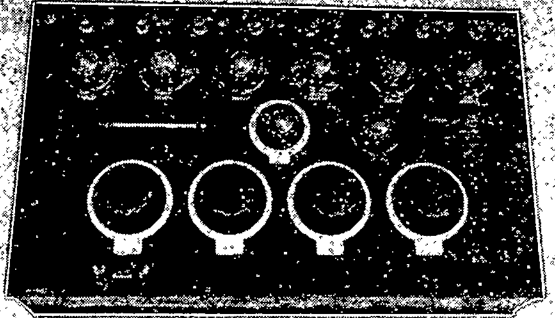
EXCEPTIONAL DISCRIMINATION



The Cambridge "Micro-Step" Precision Potentiometer is another "thoroughbred" from Cambridge Instrument Company. It has very great discrimination over a *single* range of 2 volts, and is designed to meet the requirements of high sensitivity *plus* precision, *plus* wide range.

Readings are in steps of 0.1µV up to 2 volts and the instrument is constructed in the form of a double potentiometer, but requires only one galvanometer.

The instrument has been designed to minimise the thermal EMFS generated, and these are extremely small indeed.

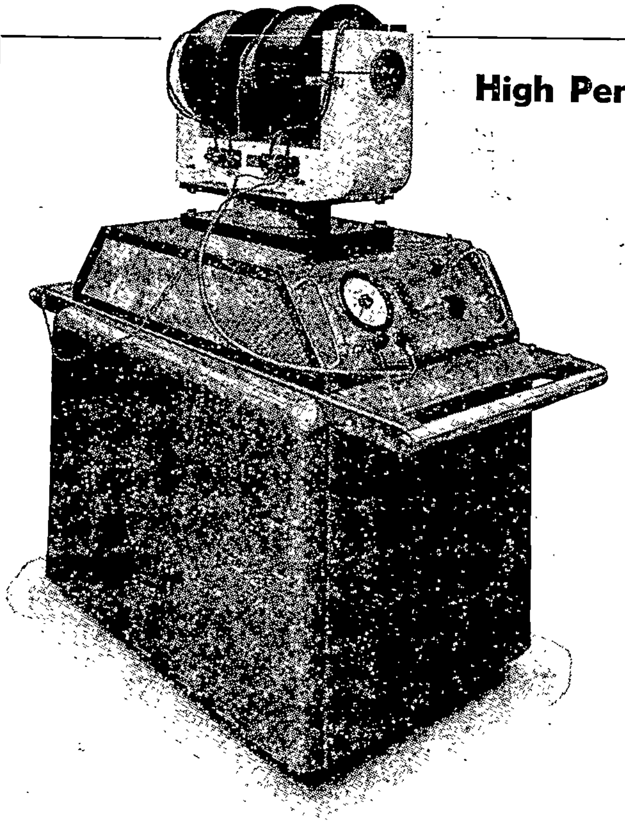
Write for List S.A.295N. For future publications, ask for Mailing Form N/7/61.

SPECIFICATION:

Range: 2 volts.
Discrimination: One part in 20,000,000.
Accuracy: Better than ± 0.001% on 2 volt dial.
Smallest Direct Reading: 0.000 0001 volt.
Temperature compensation for standard cell from 10°C to 35°C.

Cambridge "MICRO-STEP" PRECISION POTENTIOMETER

CAMBRIDGE INSTRUMENT COMPANY LTD • 13 GROSVENOR PLACE, LONDON SW1



High Performance ELECTROMAGNETS and Power Supplies

RUGGEDNESS

4″ Electromagnet Type A (4″ pole diameter)
Fields up to 25,000 gauss.
Homogeneity of at least 1 part in 10^5 in ½ cc.

ROTATION

Rotating Base Type AE
360° scale.
Positive friction lock.

STABILITY

Current-Stabilized Power Supply Unit Type B.

Also available:

1½″ Electromagnet Type C—for Teaching purposes.
7″ Electromagnet Type E—for Electron Resonance Work.
8″ Electromagnet Type D—for Electron Resonance and Nuclear Magnetic Resonance Work.
Direct Reading Magnetometer Type G.
Proton Resonance Magnetometer Type P.

gonial production frequently continues until July, particularly on plants where fertilization has failed. In the latter circumstances the number of archegonia produced is frequently increased to double the normal number. Where sporophytes have formed these are usually apparent by the end of July, covered by the white calyptra. The capsule takes shape in August and September, is fully formed by December, and matures to dehisce in March or April (Table 9).

Table 9. FIELD OBSERVATIONS OF THE MATURATION CYCLES OF *Polytrichum* SPECIES (J. G. HUGHES, 1955)

Developmental phase	*P. aloides*	*P. piliferum*
Sex organs mature	Early March	April
Vegetative phase of sporophyte	Short	Long
Onset of reproductive phase of sporophyte	May	November
Mature sporogonia	August	Following March
Capsules dehisced	Following spring	Early summer

Polytrichum piliferum

Date	Average length of apical meristem (cm.)	Developmental phase
Oct. 5	0·030	Vegetative, endothecium unsegmented
Oct. 23	0·035	Apical cell ceased to divide; endothecium segmented
Nov. 23	0·060	Endothecial block starts to swell at base; apical cell begins to vacuolate
Dec. 21	0·070	Little change
Jan. 18	0·085	Operculum and theca clearly demarcated
Feb. 15	0·110	Archesporial layer differentiated
Mar. 15	0·150	Archesporial tissue several cell layers thick; peristome apparatus developing
April 12	0·450	Sporangium fully developed

Female plants placed in experimental chambers in January under long- and short-day conditions, combined in each case with temperatures of 70° F. and 50° F., produced archegonia within two weeks in both long and short days, about 66 per cent responding in each case. Even after a month the plants in both cabinets at 50° F. were still vegetative (Table 10). From these results, it was concluded that day-length was not the governing factor in the production of sex organs in *Polytrichum aloides*, but that the rise in temperature in the spring months in the field may be the most important factor causing the sudden appearance of sex organs.

Table 10. PHOTO-PERIODIC RESPONSES IN *Polytrichum aloides* (J. G. HUGHES, 1955)

Period of response (days)	18 hr.		6 hr.	
	70° F.	50° F.	70° F.	50° F.
14	66 per cent response	—	66 per cent response	—
28	—	No response	—	No response

Twenty-five gametophytes (female) used in each case. Experiment conducted in January.

A second experiment was set up involving diurnal fluctuations of temperature in combination with the two photo-periods. By these experiments it was hoped to indicate whether the temperature stimulus was a light or dark reaction. The results indicated that there was a slightly greater response in the warm nights than in the cold (Table 11). A temperature stimulus of 20° F. proved sufficient to induce the development of archegonia in the laboratory two months before their earliest appearance in the field.

The sporophyte grows by means of an apical cell until a branch is formed. This does not enter into the reproductive stage until the apical cell loses the power to divide, and the whole original meristem is then incorporated into the developing sporangium.

Table 11

Response (per cent)	Light (hr.)	Temperature of light period (°F.)	Dark (hr.)	Temperature of dark period (°F.)
54	18	70	6	50
70	18	50	6	70
44	6	70	18	50
60	6	50	18	70

Plants of *Polytrichum aloides* bearing vegetative sporophytes were placed in experimental chambers in June, in 8 hr. and 18 hr. light respectively at normal temperatures for the time of year. At intervals of 3, 5 and 7 weeks, the cultures were exchanged and, once changed, remained in that cupboard up to a total period of 24 weeks. By sectioning ten sporophytes from each group, and measuring the total seta length and total meristem length, it was found that short days stimulated development of the capsule and spore production. Long days did not entirely inhibit spore production, but did have a distinct retarding effect on sporangium development. The length of the seta was also found to be influenced by the photoperiod, since in short days the vegetative stage is very limited, giving rise to a short seta, whereas in long days there is a late change to the reproductive phase and so a long seta is formed. To ascertain whether this was due to an increase in the number of cells, or to cell length, the setæ of both long- and short-day sporophytes were macerated and measured. Cells from the central strands were used as these were not as spiralled as the outer cells of the setæ. An average of 200 cells of each kind of seta (Table 12) indicated that it is a difference in cell length and not in cell number which causes the difference in seta length. It was concluded that *Polytrichum aloides* is only facultatively photo-periodic in spore production since, although spore production is markedly promoted in short days, it can also be finally achieved even in long days.

Table 12

Day-length	Response	Average length of 200 cells in seta (arbitrary units)
18 hr.	Slow*	3·71
6 hr.	Rapid*	2·61

* The true vegetative state is taken when the average meristem length is 0·04 cm.; the true reproductive state is taken when the average meristem length is 0·114 cm.

Polytrichum piliferum differs in that the sporophytes do not mature until March of the following year, so that sporangia pass through a cold winter period (in contrast to *Polytrichum aloides* where sporangia are mature in August of the same year) (Table 9).

Plants bearing vegetative sporophytes were removed from the field at monthly intervals, to growth chambers at 70° F., half being submitted to long days and half to short days, the field behaviour of the plants being studied as a control. Plants from collections made in October did not produce sporangia in the experimental chambers, although apical growth had ceased and some segmentation had occurred. This suggests that the character of the sporophytes as a branch of limited growth is inherent in the sporophyte itself and not contingent on environmental factors. Collections made on November 23 and afterwards, gave rise to small, normal capsules in both day-lengths. It was concluded that sporangium development was indifferent to day-length and that *Polytrichum piliferum* probably has a low-temperature requirement in its spore production which is normally satisfied in the field from late November onwards.

CARBON DIOXIDE AND ETHANOL AS FACTORS CONTROLLING THE GROWTH OF ETIOLATED OAT SEEDLINGS

By Dr. C. L. MER
A.R.C. Unit of Plant Physiology, Imperial College of Science and Technology, London, S.W.7

When the airstream passing over etiolated oat seedlings is enriched with carbon dioxide to a concentration of 5 per cent for 3 days from the time of planting, then during the 5 days following cessation of treatment with carbon dioxide, the growth of the seedlings is modified in the following respects: (1) the mesocotyl, after an initial depression, shows a marked promotion[1-3]; (2) the coleoptile is depressed[1-3]; (3) the amount of reserves transferred from the endosperm to the embryo is reduced[2,6]; and (4) the mesocotyl retains a capacity to elongate after a brief exposure to light[4,5]. In the absence of carbon dioxide in the airstream, identical growth variations can be induced to occur during the interval mentioned, by treating the seedlings with 0·3 per cent ethanol through the roots for 3 days from the time of planting (references as above) and further, when the ethanol and carbon dioxide treatments are administered simultaneously, their effects on mesocotyl growth are independent and additive[4].

The coincidence between these effects on growth suggests that a single phenomenon may be under investigation, that is, the ethanol absorbed from the culture medium (London tap-water) might give rise *in vivo* to carbon dioxide to which both effects should be attributed; or, alternatively, treatment with carbon dioxide might induce ethanol formation, perhaps by occasioning a fermentative change in metabolism; in this event the growth responses observed should be regarded as ethanol effects.

The data to be presented favour the first alternative.

The effect of treatment with ± 5 per cent carbon dioxide combined factorially with ± 0·3 per cent ethanol on the ethanol content of 3-day-old seedlings has been determined on 10 replicate samples, each of 5 plumules, by distilling the volatile constituents under reduced pressure into an aliquot of acid dichromate and titrating the residual dichromate with sodium thiosulphate.

The mean ethanol contents, in µgm. per 5 plumules, are recorded in Table 1, exp. 1. It will be seen that treatment with ethanol alone increased the content in the plants, but the overall effect of ethanol on the internal content, as shown in the analysis of variance, did not reach significance. This was due to the highly significant negative interaction with carbon dioxide, which when administered alone reduced the amount of ethanol in the plumules but apparently did so more effectively when ethanol was additionally supplied.

Because of the variation in growth with treatment, determination of the ethanol in a given number of plumules means that different weights of material were assayed. As these samples were collected in darkness no correction could be made for the differences, but in a further experiment, the 5 plumules in each sample were briefly exposed to light for measurement. The ethanol contents were determined and submitted, as previously, to an analysis of variance (Table 1, exp. 2). Additionally, the total lengths of the mesocotyl + coleoptile + leaf of the 5 plumules in each treatment are quoted in italics, together with an analysis of covariance. From these length-measurements the content of water was estimated so that the concentration of ethanol in the plumules could be assessed. The content in µgm. and analysis of variance agreed with those of exp. 1, but the analysis of covariance shows that by allowing for variation in length, the depressive effect of carbon dioxide on the ethanol content of the seedlings was eliminated while the levels of significance due to applied ethanol and its negative interaction with carbon dioxide were both increased.

Table 1. Ethanol Content (in µgm./5 Plumules) of 3-day-old Oat Seedlings, after Treatment for 3 days in Darkness with ± Carbon Dioxide (5 per cent) combined with ± Ethanol (0·3 per cent)

Mean values of 10 replicates in µgm. Exp. 1, plants not exposed to light; exp. 2, plants exposed on the third day for measurement; the lengths of mesocotyl + coleoptile + leaf (in mm.) are quoted in italics

Treatment: Carbon dioxide	+	+	−	−
Ethanol	+	−	+	−
Exp. 1	6·74	9·05	15·56	13·73
Exp. 2	10·17	11·53	21·31	16·95
	122·4	*211·2*	*177·5*	*283·3*

Variant	Analyses of variance of ethanol content			Analysis of covariance (total length and ethanol content)	
	DF	Mean squares Exp. 1	Exp. 2	DF	Mean square Exp. 2
Carbon dioxide	1	455·6 ↓	685·6 ↓	1	0·9
Ethanol	1	0·6	22·5 ↑	1	138·8 ↑
Carbon dioxide × ethanol	1	42·5 ↓	81·8 ↓	1	137·8 ↓
Error	36	5·1	7·8	35	4·7

The arrows indicate the direction of the effect.
DF, degrees of freedom.

The mean percentage concentrations of ethanol (w/w) in these plumules were as follows: carbon dioxide and ethanol, 0·0096; carbon dioxide, 0·0063; ethanol, 0·013; controls, 0·0066. Evidently, the ethanol concentration within those plants treated with it did not approach that supplied externally. Further, treatment with carbon dioxide depressed the *in vivo* accumulation of ethanol when this was also administered in the culture medium, although under these conditions the content was higher than in the controls, indicating that some entry had occurred. Finally, as the same concentration of ethanol was present in the controls and under carbon dioxide, this treatment neither promoted the *in vivo* synthesis of ethanol nor did it bring about the decomposition of that occurring naturally.

The operation of this negative interaction between carbon dioxide and ethanol becomes clearly manifest when higher concentrations of ethanol are used in this type of experiment. In Fig. 1 are shown graphically the mean lengths of the mesocotyls and coleoptiles of etiolated oat seedlings, from eight treatments of a 2^3 factorially arranged experiment employing ± 0·5 per cent ethanol and ± 5 per cent carbon dioxide, both applied for 3 days from the time of planting, combined with exposure to dim red light (about 1 ft. candle) for 5 min. on termination of treatment with carbon dioxide and ethanol, when all seedlings were transferred in darkness to tap-water. The measurements of the third-day samples estimated the lengths of the plant organs at the time of exposure to light, and the differences in growth during the subsequent 5 days, displayed in the graphs, were after-effects.

In darkness (Fig. 1*A*) carbon dioxide (squares) initially reduced growth of the mesocotyl but afterwards occasioned a promotion, while 0·5 per cent ethanol alone (triangles) severely inhibited growth both during and after treatment. When, however, carbon dioxide was also administered, the initial depression of the mesocotyl due to ethanol gave way to rapid growth so that, ultimately, a length was attained equal to that reached in carbon dioxide alone (diamonds). The effect of illumination can be assessed by comparing the controls in Fig. 1, *A*, *B* (solid and open circles respectively); after exposure some elongation occurred, but more growth was shown by the mesocotyls of those plants treated with carbon dioxide. Ethanol alone severely inhibited growth, and again, simultaneous treatment with carbon dioxide relieved the inhibition so that a length was reached equal to that in carbon dioxide alone.

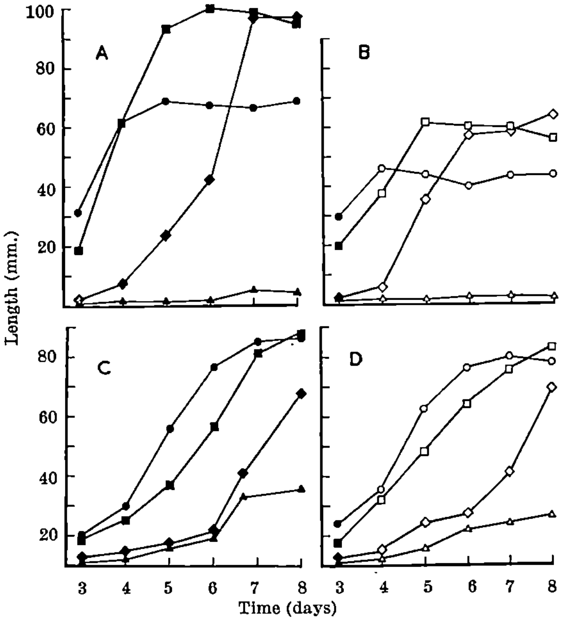

Fig. 1. Growth on successive days of mesocotyls and coleoptiles in darkness (*A* and *C*) and after a single exposure to dim red light for 5 min. on the third day (*B* and *D*) following treatment during the three days after planting, with: ◇ carbon dioxide + ethanol; □ carbon dioxide; Δ ethanol; O control
Solid points, in darkness; open points, after illumination

The behaviour of the coleoptiles is depicted in Fig. 1, *C*, *D* respectively, in darkness, and after exposure to light. The usual effects of light (transient promotion) and of carbon dioxide (generally depression) were recorded in this experiment. Ethanol alone inhibited growth, but again in the presence of carbon dioxide the inhibition was overcome; between the sixth and eighth days the rate of growth in darkness (1·02 mm./hr.) was approximately equal to that shown by the controls between the fourth and sixth days (0·98 mm./hr.). Similar effects were recorded for the plants exposed to light. Although the observations have not actually been made, the rates of elongation would suggest that the coleoptiles of the plants treated with carbon dioxide and ethanol together would ultimately have reached the lengths attained by their respective controls. The effect of this particular treatment may therefore be regarded as a delay in germination.

The inhibited seedlings (ethanol only) suffered no permanent injury; after transfer to water on the third day, root growth was resumed and in the last sample the second internodes were already quite long; the main apical meristem thus seems immune to externally applied ethanol.

The data as a whole suggest that ethanol has an inhibitory effect on growth which increases with the level of concentration. There is, as well, a secondary effect thought to arise from a conversion to carbon dioxide which then initiates a growth promotion. As these two effects are antagonistic the ultimate response observed will depend on the relation between these two factors. Thus, low concentrations of ethanol (0·2–0·3 per cent) are promotive whereas 0·5 per cent is inhibitory. In the first case the concentration in the tissues may not reach an inhibitory level and the promotive effect arising from its decomposition therefore appears. In the second case the inhibitory effect of ethanol masks the promotive effect of carbon dioxide.

This still leaves open the question as to why the inhibitory effect of 0·5 per cent ethanol can be eliminated by simultaneous treatment with carbon dioxide. Since both coleoptiles and mesocotyls behave in the same way some basic growth process seems to be affected by this dual treatment. The only data relevant are those in Table 1, which suggest that a high level of carbon dioxide prevents the *in vivo* accumulation of ethanol. Whether or not this is due to an activation of ethanol dehydrogenase by carbon dioxide is not at present known.

The variations in growth induced by these substances might indicate an effect on auxin metabolism, and this aspect of the problem is at present under investigation.

LETTERS TO THE EDITORS

COSMOLOGY

The Steady Universe with Charge Excess

RECENTLY, Lyttleton and Bondi[1] put forward the suggestion that the expansion of the Universe is caused by the absolute values of the charges of the proton and the electron not being equal, thereby giving a net charge to the hydrogen atom, and causing mutual repulsion in the universe, which to a first approximation may be considered as composed of a uniform distribution of hydrogen atoms. The analysis of Lyttleton and Bondi may be simplified by the use of the creation potential N suggested by Watson[2], and this simplification is the main purpose of this communication.

If there is creation, Maxwell's equations modify to

$$\nabla \times \mathbf{E} + \frac{\partial \mathbf{B}}{\partial t} = 0 \qquad \nabla \cdot \mathbf{B} = 0 \qquad (1.1),(1.2)$$

$$\nabla \times \mathbf{H} - \frac{\partial \mathbf{D}}{\partial t} = \mathbf{J} - \frac{1}{\mu_0}\nabla N \qquad (1.3)$$

$$\nabla \cdot \mathbf{D} = \rho + \varepsilon_0 \frac{\partial N}{\partial t} \qquad (1.4)$$

where the rate of creation of charge per unit volume is given by:

$$\nabla \cdot \mathbf{J} + \frac{\partial \rho}{\partial t} = \frac{1}{\mu_0}\left\{\nabla^2 N - \mu_0 \varepsilon_0 \frac{\partial^2 N}{\partial t^2}\right\}.$$

where μ_0, ε_0 are the permeability and dielectric constant respectively of free space. (The Giorgi system of units is used throughout.)

Suppose now that a steady state is assumed. All derivatives with respect to t vanish and equations (1.1) to (1.5) become

$$\nabla \times \mathbf{E} = 0 \qquad \nabla \cdot \mathbf{B} = 0 \qquad (1.6)\ (1.7)$$

$$\nabla \times \mathbf{H} = \mathbf{J} - \frac{1}{\mu_0}\nabla N \qquad (1.8)$$

$$\nabla \cdot \mathbf{D} = \rho \qquad (1.9)$$

the rate of creation per unit volume being

$$\nabla \cdot \mathbf{J} = \frac{1}{\mu_0}\nabla^2 N$$

A possible solution is clearly given by

$$\mathbf{E} = -\nabla V,\ \mathbf{H} = 0,\ \mu_0 \mathbf{J} = \nabla N,\ \rho = \varepsilon_0 \nabla^2 V \qquad (1.11)$$

and a solution of this type will be used in the next section. It will be noticed that, because of N, zero $\mathbf{H}$ is possible even when $\mathbf{J}$ is non-zero.

Suppose now that the charge on a proton is e and that the charge on an electron is $-(e - \Delta e)$. Let M be the mass of a hydrogen atom, its charge being Δe. Let n be the number of hydrogen atoms per unit volume (assumed uniform). The charge density is thus $n\Delta e = \rho_e$ and the mass density is $nM = \rho_m$.

Inside this, considered as a uniform spherical distribution the centre of which is the origin, the electric and gravitational intensities are respectively ($\mathbf{r}$ being the position vector from the origin)

$$\mathbf{E}_e = \frac{1}{3}\frac{\rho_e}{\varepsilon_0}\mathbf{r}\ , \quad E_m = -\frac{4\pi\gamma\rho_m}{3}\mathbf{r} \qquad (2.1),\ (2.2)$$

It will be observed that E_e satisfies equation (1.11) if

$$V = -\frac{1}{6}\frac{\rho_e}{\varepsilon_0}\mathbf{r}^2$$

The force on a hydrogen atom in this medium is, if $\mathbf{f}$ be the acceleration:

$$M\mathbf{f} = \Delta e \mathbf{E}_e + M\mathbf{E}_m = \frac{n}{3}\left[\frac{(\Delta e)^2}{\varepsilon_0} - 4\pi\gamma M^2\right]\mathbf{r} \qquad (2.3)$$

It follows from equation (2.3) that the sign of Δe is irrelevant. This point does not seem to have been mentioned by Lyttleton and Bondi, and so the theory applies equally well whether the charge of the electron or of the proton be the greatest in absolute value.

Using the relation between velocity and acceleration

$$\mathbf{f} = \frac{d\mathbf{v}}{dt} = \frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v}\cdot\nabla)\mathbf{v} = (\mathbf{v}\cdot\nabla)\mathbf{v} \qquad (2.4)$$

it follows that

$$\mathbf{v} = \left[\frac{n}{3M}\left(\frac{(\Delta e)^2}{\varepsilon_0} - 4\pi\gamma M^2\right)\right]^{1/2}\mathbf{r} \qquad (2.5)$$

In order to obtain the proper behaviour at the origin, the arbitrary constant is put zero. This represents in the large a recession outwards with a velocity directly proportional to the distance. If the negative root were taken there would be an approach instead of a recession.

$$\mathbf{v} = \frac{\mathbf{r}}{\tau} \qquad (2.6)$$

where τ is the Hubble time.

The current flow vector associated with the field distribution discussed in section 2 is:

$$\mathbf{J} = \rho_e \mathbf{v} = n\Delta e \mathbf{r}/\tau \qquad (3.1)$$

Thus the rate of charge creation per unit volume is

$$\nabla \cdot \mathbf{J} = \frac{3n\Delta e}{\tau} \qquad (3.2)$$

This is equivalent to a rate of production of $3n/\tau$ hydrogen atoms per unit volume in agreement with Lyttleton and Bondi. Were the negative root taken in (2.5), there would be annihilation instead of creation of matter.

One further consequence of experimental data may be noted, as it does not seem to have been referred to by Lyttleton and Bondi. There is experimental reason to believe that[3]

$$\frac{8}{3}\pi\gamma\rho_m\tau^2 = U^{-1} \qquad (4.1)$$

where U is a number the value of which is about unity. It follows, therefore, that

$$U^{-1} = \frac{8}{3}\pi\gamma n M\left[\frac{n}{3M}\left(\frac{(\Delta e)^2}{\varepsilon_0} - 4\pi\gamma M^2)\right)\right]^{-1} \qquad (4.2)$$

whence

$$\frac{(\Delta e)^2}{4\pi\varepsilon_0} = \gamma M^2(2 + U) \qquad (4.3)$$

This implies that the electrical repulsion between two hydrogen atoms must be at least twice the gravitational attraction. Were U unity, it would be 3 times, and were the repulsion 5 times the attraction, as suggested by Lyttleton and Bondi, this would imply that $U = 3$.

I am indebted to Dr. R. A. Newing for discussions.

PHYSICS

Topology of Linear Neutron Kinetics

IN the theory and interpretation of pulsed neutron measurements and in the analysis of random fluctuations in a nuclear fission reactor it is often helpful to study the kinetic behaviour of the time-dependent, space-independent model of the multiplying assembly.

For this purpose the neutron kinetics may be formulated as an integral equation as opposed to the more conventional set of first-order differential equations. This has some advantages in that: (i) The kernel functions of the Volterra-type integral equation have immediate physical significance. (ii) The integral equation is logically related to the topological representation of the fission process. It is also related in structure to the generating functions of probability theory. (iii) Numerical computation of resolvent kernels is usually more efficient than forward integration. (iv) Extension of the theory to non-stationary reactor kinetics and non-linear reactor topology is obvious.

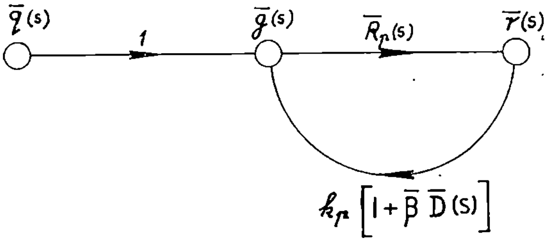

Fig. 1. k_p, Effective prompt multiplication constant; $\bar{q}(s)$, extraneous neutron source; $\bar{g}(s)$, mean generation rate of total importance; $\bar{r}(s)$, mean prompt regeneration rate of total importance; $\bar{R}_p(s)$, prompt importance regeneration kernel; $\bar{\beta}$, delayed neutron fraction; $\bar{D}(s)$, delay distribution function

The role of a nuclear reactor as a 'neutron amplifier' has been shown by Schmid[1]. His signal flow graph for linear topology in the frequency domain is given in Fig. 1. The integral equation of neutron kinetics then takes the form:

$$\frac{r(t)}{r_0} = 1 + \int_0^t G(t-\tau)\rho(\tau)\frac{r(\tau)}{r_0}d\tau \qquad (1)$$

where $G(t)$ is Green's function of neutron kinetics and, for the case of stationary kinetics, obeys the following relationship:

$$G(t) = L^{-1}\left[\frac{1}{s\{F(s)+\tau\}}\right] \qquad (2)$$

where

$$F(s) = \frac{1}{s}\left[1 - D(s)\right] \qquad (3)$$

and

$$\tau = \frac{l}{\bar{\beta}k_p} \qquad (4)$$

and

$$\rho = \frac{k_p - 1}{\bar{\beta}k_p} - 1 \qquad (5)$$

l being the mean neutron generation time.

On the basis of this theory, the computation of reactor frequency and transient responses is carried out completely automatically on a digital computer. Step, pulse, ramp, sine and arbitrary time-responses can be studied for fixed, circulating fuel and boiling-water reactors.

In Fig. 2 some solutions of the integral equation are given for linear variations in reactivity. The frequency responses of a boiling water reactor are given in Fig. 3 and Fig. 4.

Molecular Emission Spectroscopy from 2μ to 12μ by a Michelson Interferometer

THE combination of a two-beam interferometer and Fourier transformation has a great advantage over conventional spectrometers in the effective use of available energy[1,2]. Further, when the interferometer is of a type which has circular symmetry like Michelson's, there is another gain[3], giving the Michelson–Fourier combination an effective luminosity that is the highest of all known spectroscopic systems[4]. It is most advantageously used in wave-length regions where the limit to the spectroscopic resolution obtainable in a given time of observation is set by detector noise. So in the infra-red region, considerable improvement in spectra over those given by conventional methods is to be expected. This has been realized in practice in the very near infra-red[5] and in the far infra-red[6,7]. This communication describes its application in the 2–12μ region, where many molecular vibrational bands are found.

To test the system, experiments have been made to obtain emission spectra of gases at relatively low temperature in cases where the spectra are well known from absorption measurements. The gas was contained in a heated cell with rock salt windows and, after chopping, the radiation passed through a Michelson interferometer to a detector, as shown diagrammatically in Fig. 1. The interferometer was designed and constructed for this work by the Light Division, National Physical Laboratory. It has, as special features, an optically worked glass slide to constrain the moving mirror, and disks of barium fluoride 10 cm. in diameter for the beam splitter and compensator plates, but details of this instrument will be the subject of a separate communication. Measurement of the displacement of the moving mirror to get path-difference was made by illuminating part of the interferometer field with mercury ($\lambda = 1{\cdot}014\mu$) radiation and recording fringes by a photomultiplier. The interferogram of the radiation of the emitting gas was sampled at equal intervals of path-difference by a signal derived from the record of the mercury fringes. The values of intensity at these points were digitized and punched on paper tape suitable for input to the digital computer *Ace*, where a programme for Fourier transformation gave the spectrum.

Fig. 2 shows part of the ν_2 band of ammonia obtained in this way. For this spectrum, the gas temperature was 70° C., the pressure was 11 mm. mercury and the detector was a Unicam Golay cell fitted with an indium antimonide filter. The maximum path-difference introduced was 2 cm., this limit being imposed by the fall-off in visibility of the 1·014μ mercury fringes. This is attributable to the rather

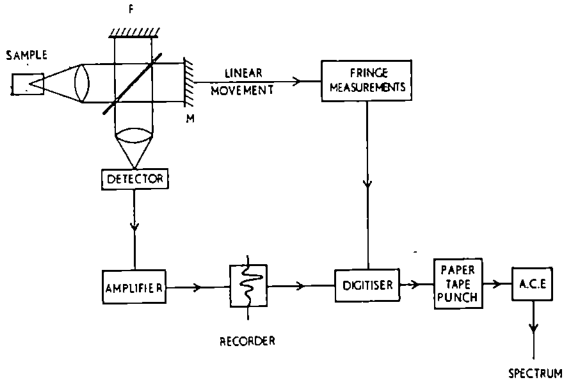

Fig. 1. Diagram of the arrangement of a Michelson interferometer used for emission experiments where the interferogram is digitized and recorded in a form for computer input

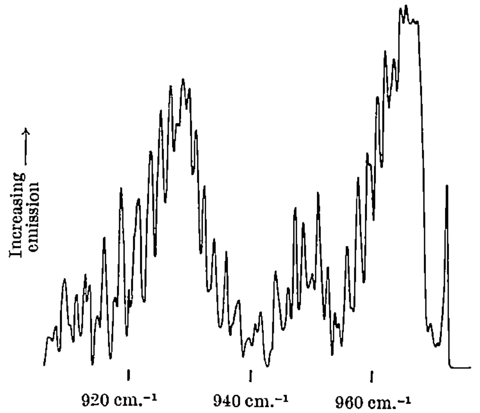

Conventional absorption spectrum

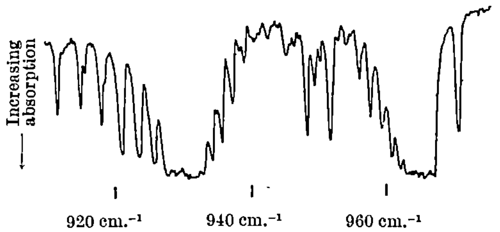

Fig. 2. Spectrum of part of the ν_2 band of ammonia in emission. The gas temperature was 70° C. and its pressure 11 mm. mercury in a cell of 10-cm. length. Below is shown a conventional absorption spectrum

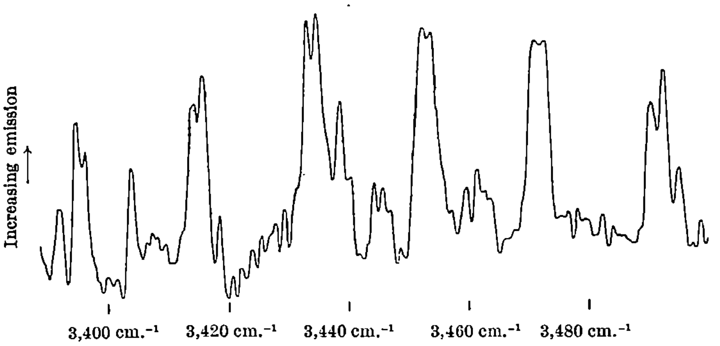

Fig. 3. Part of a spectrum near 3μ of ammonia in emission. The gas temperature was 75° C. and the pressure 600 mm. mercury in a 10-cm. cell

high pressure in the lamp used (Osram type *MBD* 125 W.). Following the convention which was adopted in far infra-red work[6], we define the resolution to be the reciprocal of the maximum path-difference, giving in this case a value of 0·5 cm.$^{-1}$. This is a restrictive definition, as may be seen by comparing the actual resolution of the emission spectrum with the conventional absorption spectrum shown below it. The latter was chosen from the literature[8] as most closely matching our resolution and pressure conditions. The resolution claimed for it is 0·4 cm.$^{-1}$, and it can be seen that the resolution in the emission spectrum is slightly better. When a comparison is made with the recent measurements of this band of ammonia at higher resolution by Mould, Price and Wilkinson, it is found that our resolution approaches their value of 0·1 cm.$^{-1}$, but the much lower gas pressure used in that work makes an exact comparison difficult.

The emission interferogram was recorded in about 1 hr. and the time taken by the *Ace* computer to calculate the part of the spectrum shown was about 15 min. The output of the computer is plotted automatically on a recorder, and the figures shown are direct reproductions of these plots.

Comparison with an emission spectrum made with a prism spectrometer[9] shows that much superior resolution and signal-to-noise ratio is possible with the interferometer in comparable times of observation.

Fig. 3 shows a small part of the spectrum of ammonia in emission near 3μ. Here the gas was at a temperature of 75° C., the pressure was 600 mm. mercury in a 10-cm. cell and the detector used was a lead sulphide cell with a germanium filter. The maximum path-difference was about 1·6 cm., giving a resolution of 0·6 cm.$^{-1}$. In this case it has not been possible to provide a suitable absorption spectrum for comparison, because in this region[10] three bands, ν_3, ν_1 and $2\nu_4$, all overlap and intensity distributions vary greatly. However, one expected feature, namely, the inversion splitting[11], can be seen in all the strong lines, despite the rather high gas pressure that was used.

From these results it can be seen that the Michelson–Fourier combination offers new prospects for the emission spectroscopy of sources of low brightness. The instrument described here is now being used for work on night-sky emission and also for observations on planetary atmospheres. Another possibility being investigated is the application to Raman spectroscopy with excitation lines of longer wave-length than those normally used. Finally, it is thought that advantages of this system, giving as it does the maximum product of solid angle and resolution, may be of importance in applications to artificial satellites, where the time-efficiency of the initial measurement of the radiation outweighs the disadvantage of having to compute the spectrum.

Pressure Differences in a Direct-Current Capillary Discharge

This communication deals with the difference of pressure which arises between the ends of the capillary of a d.c.-excited krypton discharge lamp as a result of the motion of ions and electrons in the electric fields[1] of the discharge. The effect is of importance in view of the adoption of the 0·606μ line emitted by krypton-86 as the new standard of length[2]. The wave-length of this line can be shifted, because of broadening due to pressure, by an amount which depends on the pressure and the current in the discharge; this shift is of the order of one part in 10^8 under the conditions for excitation by means of a d.c. discharge, which have been recommended by the International Committee of Weights and Measures[3].

The measurements were made by means of a special lamp, which is illustrated schematically in Fig. 1. The form of this lamp was basically the same as that recommended for excitation of the primary wave-length standard, having a capillary of 3 mm. internal diameter and 90 mm. length. However, instead of a single hot cathode, two were provided, one at each end of the capillary, so that the d.c. discharge could be run in either direction. A Pirani gauge head was connected to each end of the capillary, for the measurement of the pressure, and a side-tube connected to one of the ends enabled control of the vapour pressure of the krypton by the use of a

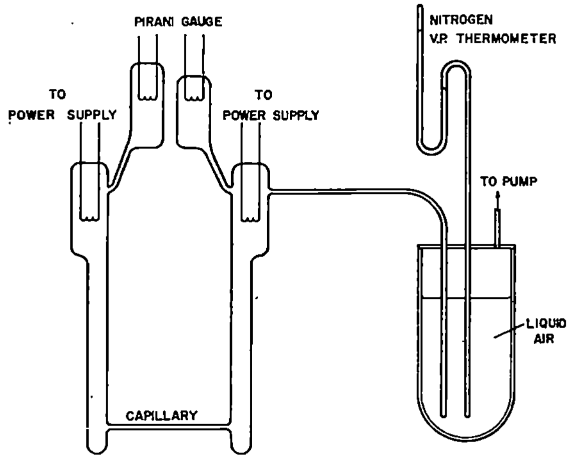

Fig. 1

cryostat. A nitrogen vapour-pressure thermometer was used to measure the temperature of the cryostat, and the resultant vapour pressure of krypton in the side-tube was deduced from the Meihuizen formula[4]. Although the pressure at one end of the capillary was controlled by the vapour pressure of krypton in the side-tube, which was held at temperatures down to 61° K., the temperature of the capillary itself was controlled by immersion in nitrogen at its normal boiling point.

The results of the measurements for a range of pressures and currents are shown in Fig. 2. The large relative differences of pressure between the two ends of the capillary are quite striking. Of particular interest in connexion with the primary wave-length standard is the pressure difference under the operating conditions as now recommended, namely, a current density of 3·0 m.amp./mm.^{2} with the krypton pressure controlled by its vapour pressure at the anode end, the temperature of which is at the nitrogen triple point. In this case the pressure is 32μ at the anode end and 21μ mercury at the cathode. According to typical values given for the shift due to pressure of the 0·606μ line of krypton-86 (ref. 5), the wave-length emitted by the gas in the discharge will vary along the length of the capillary by about 2·5 parts in 10^9. When the lamp is observed end on, as recommended at present, the possible error in the wave-length is not large compared with the accuracy specified by the International Committee (< 1 in 10^8), but it is clear that the effect must be taken into account if much greater accuracy is attempted with this form of source.

METEOROLOGY

Radar Reflectivities of Hail Samples

In the past few years quantitative measurements have been made of the radar reflectivity of many storms, particularly severe ones in which hail and even tornadoes have occurred. In particular, Donaldson has published and discussed vertical profiles of reflectivity of storms in the eastern United States[1]. He finds that the absolute magnitude of the reflectivity increases with the severity of the thunderstorm in the sequence rain, hail, large hail and tornadoes; and that in hail and tornado situations, the maximum reflectivity is found aloft at a height which increases with storm severity.

The proper interpretation of such observations clearly depends on an understanding of the characteristics (as radar targets) of hail, both wet and dry. Recent computations by Herman and Battan[2] and measurements by Atlas *et al.*[3] have shed light on the problem of radar scatter by hail (particularly large hail); and Atlas and Ludlam[4] have calculated the reflectivities of hail of various size-spectra. The question arises as to exactly what size-spectra do in fact exist, and the reflectivities which can be expected from such spectra.

Power returned to the radar is proportional to the reflectivity of the target, that is, to the sum of the back-scattering cross-sections. For spherical target elements of diameter much less than the radar wavelength (Rayleigh scattering) the back-scattering cross-section is proportional to the sixth power of the particle diameter, of which the sum (ΣD^6) is called Z, the reflectivity factor[5]. It has become customary to examine Z in relation to precipitation-rate and liquid water (or ice) content in the cases of rain and snow in which Rayleigh scattering applies. Where hailstorms are concerned it is useful in making comparisons to describe the reflectivity of a storm in terms of the equivalent reflectivity factor Z_e, that is, that value of ΣD^6 which, assuming Rayleigh scattering from spherical water drops, would yield the same reflectivity as is in fact observed.

In the course of a hailstorm-observing programme * in western Canada (Alberta), 28 samples of hail were collected. Each sample represents all the hail which fell on a small area (of the order of 0·05 m.^{2}) during a hailstorm. The samples were collected from points over a wide area and on many different days; they represent a wide range of rates of hail-fall (0·02–40 mm. hr.$^{-1}$, melted) and of ice concentrations (0·01–6 gm. m.$^{-3}$). For each sample, Z_e was computed on the basis of reflectivities derived by Atlas and Ludlam[4] for both wet and dry hail at radar wave-lengths of 3·3 and 10 cm. Each of the 28 values thus computed was plotted against the corresponding value of R, the rate of precipitation of the hail as observed at the ground.

Fig. 1 shows the plot of Z_e versus R, for both wet and dry hail at wave-length 3·3 cm. The straight lines show the least-squares regressions, expressed by the equations:

$$Z_e = 4 \times 10^4 R^{0.88} \text{ (wet hail)}$$
$$Z_e = 1 \times 10^4 R^{1.08} \text{ (dry hail)}$$

Z_e being in mm.^{6} m.$^{-3}$ and R in mm. hr.$^{-1}$. Clearly, for the radar wave-length considered and for these particular hail distributions, wetting of the hail enhances Z_e by a factor of from 2 to 4. According to the recent reflectivity data mentioned above[2-4], such an enhancement is to be expected when the major contribution to the total reflectivity of the sample is made by hail of diameter less than about 1·5 cm. This is in fact the case in the Alberta samples where, in 21 of the 28 samples, 75 per cent of the total reflectivity at 3·3 cm. wave-length was contributed by hail of diameter less than 1·6 cm.

The regression lines are reproduced in Fig. 2 (d and e) with the corresponding ones for wave-length 10 cm. (b and c). Also shown (a) is the relation between Z ($= \Sigma D^6$) and R for the same 28 samples.

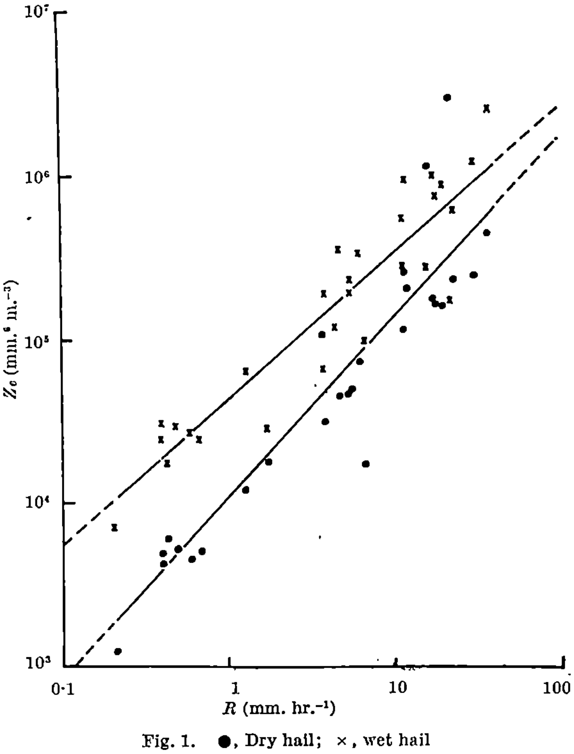

Fig. 1. ●, Dry hail; ×, wet hail

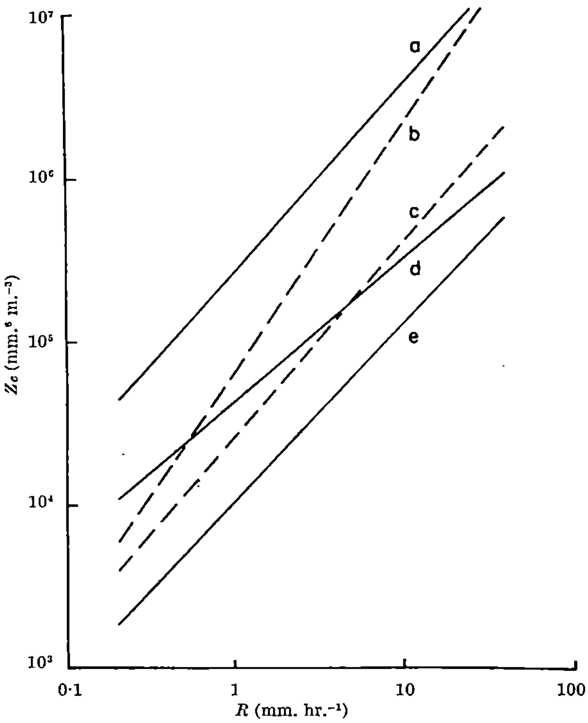

Fig. 2. a, $Z = \Sigma D^6$; b, Z_e wet 10 cm.; c, Z_e dry 10 cm.; d, Z_e wet 3·3 cm.; e, Z_e dry 3·3 cm.

This last relationship will clearly lead to an under-estimate of hailfall-rate on the basis of power returned to the radar. As in the case of the 3·3 cm. wave-length, so also does wetting of the hail enhance the reflectivity at the longer wave-length, particularly at high precipitation-rates.

Table 1. EQUIVALENT REFLECTIVITY FACTOR Z_e, MM.^{6} M.$^{-3}$

	LQ	M	UQ
Donaldson (ref. 1)	1.5×10^5	10^6	4×10^6
Alberta (wet)	3×10^4	2×10^5	5×10^5
Alberta (dry)	8×10^3	6×10^4	2×10^5

Donaldson[1] has published vertical profiles of the median (M), the lower (LQ) and the upper quartile (UQ) values of Z_e for hailstorms measured by means of 3·3 cm. radar, and it is of interest to compare values taken from his curves at a low level (5,000 ft.) with the Alberta values for the same wave-length (see Table 1). The Alberta values are lower than Donaldson's by factors between 5 and 20. The agreement may very well be better in view of doubts as to the calibration of Donaldson's radar; in fact, a reduction of his values by a factor of 6 is suggested by Atlas and Ludlam[4].

METALLURGY

Hydrogen Reduction Characteristics of Natural and Artificial Hæmatites

Published data on the rate and mechanism of the reduction process in iron oxides are frequently discordant. This lack of agreement is exemplified by two recent studes[1,2]. McKewan[1], for example, has reported the rate of reduction of hæmatite spheres in the size-range 0·6–2·5 cm. to increase continuously from 400 to 1,050° C. I found[2], however, that hæmatite particles in the size range 0·002–0·008 cm. showed a rate maximum at about 550° C. and a pronounced rate minimum at 700° C. approximately.

Since this difference in behaviour could be due to a particle-size effect, an apparatus-effect or to different physical properties of the materials, it was decided to repeat the work eliminating the first two of these variables, and using hæmatites similar to those employed in the two investigations in question[1,2].

For one series, approximately spherical particles of artificial hæmatite, 0·03 cm. diameter, were prepared by rolling pigment grade ferric oxide (as used by McKewan) in a jar for 1 hr. A screened fraction of this material was fired, in a platinum boat, for 2 hr. in an atmosphere of oxygen at 1,370° C. and then cooled slowly in oxygen to room temperature.

For the other parallel experiments, particles similar in size and shape to the artificial hæmatite were obtained by screening a washed natural hæmatite from Yampi Sound, Western Australia. Part of this material was subjected to the same treatment as the artificial hæmatite and another portion was dried in air at 110° C.

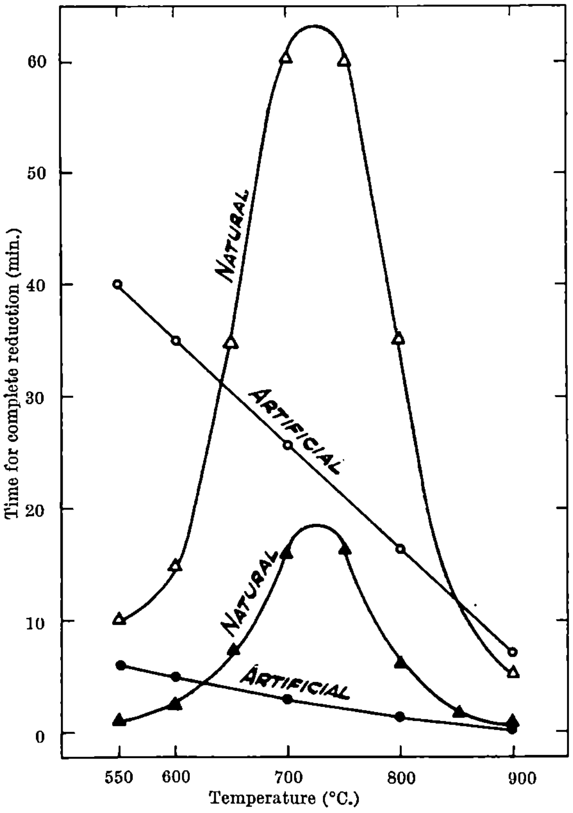

Fig. 1. Dependence on temperature of hydrogen reduction-rate for natural and artificial hæmatites. Δ, 0·03 cm. natural hæmatite, fired at 1,370° C. or dried at 110° C.; ▲, 0·003 cm. natural hæmatite dried at 110° C.; ○, 0·03 cm. artificial hæmatite fired at 1,370° C.; ●, 0·003 cm. artificial hæmatite dried at 110° C.

Particles of both artificial and natural hæmatite, approximately 0·003 cm. diameter, were also prepared from screened fractions of the raw materials and dried in air at 110° C. Using a procedure described in ref. 2, 100-mgm. samples of the various materials were reduced in a stream of hydrogen flowing at 2,000 ml./min. The distinctly different results given by the natural and artificial hæmatites are shown in Fig. 1.

In Table 1 some physical properties of the two hæmatites are shown. Both materials are weakly magnetic, and heating them to 500°, 700° and 900° C. respectively, in nitrogen, and quenching, did not alter significantly the lattice parameters shown in Table 1. The only significant differences found so far in the two hæmatites are that, under reflected polarized light, the artificial material shows a pronounced 'sub-structure', while the natural hæmatite shows none and the small amount of gangue material (mainly silica and alumina minerals) present in the natural hæmatite occurs as separate particles, whereas in the artificial material it is present with ferric oxide as composite particles.

Table 1. Physical Properties of Hæmatites

Property	Hæmatite	
	Natural	Artificial
Fe_2O_3 content (weight per cent)	99·1	99·5
Density (gm./cm.³)	5·20	5·10
Hexagonal parameters (Å.) *a*	5·035	5·033
c	13·75	13·75
Crystallinity*	Monocrystalline	Polycrystalline

* Reflected polarized light examination.

It has been clearly demonstrated that the origin of a hæmatite may influence markedly the dependence on temperature of its hydrogen reduction-rate. Until the reasons for this differing behaviour are discovered, it is apparent that care must be exercised in interpreting or comparing reduction data for hæmatites from different sources.

Thanks are due to Mr. I. D. Gray for experimental assistance and to Dr. H. K. Worner, director of research, for permission to communicate this work.

ENGINEERING

Power Requirements and Scale-up in Flotation

As part of a systematic programme for correlating mineral engineering process variables[1,2], flotation machines are now being investigated. There is no need to stress the engineering importance of the flotation process. First applied more than fifty years ago for the recovery of fine sulphide minerals from Australian gravity plant tailings, to-day it is the only method for treating the major base metal sulphide ores, and is becoming of increasing importance for non-metallic ores and coal. As a mineral engineering operation, it is often second only to fine grinding in power consumption. Despite this, empiricism largely prevails from choice of equipment to control of process variables.

Relationships between cell capacity, energy input, and flotation-rate have been suggested[3,4], and there are indications that cell power intensity and capacity are related[5]. However, the function of power in the flotation cell should not be misinterpreted. Apparatus of this type are essentially dissipative mechanisms in which the energy input ultimately appears as heat; any useful function (in this case, a separation of minerals) is incidental. Similar behaviour has been pointed out in connexion with ball milling[1], where the power is utilized in rotating an eccentric load, a negligible portion going into comminution. However, the power dissipation-level is responsible for the particular fluid-flow regime maintained within the cell, and this in turn is related to phenomena leading to flotation such as gas dispersion, particle suspension, and bubble-particle aggregation. Hence, the energy dissipation-rate which is related to the power requirements of the flotation impeller should be useful in correlating flotation cell performance with design factors.

For the present, flotation performance will not be considered beyond expressing the view that, once the power requirements can be related to the geometry and other mechanical features of cells, performance can then be related to the appropriate power number or index. The problem to be considered thus resembles the more familiar one of mixer evaluation in the chemical processing field, where correlations, using Power, Reynolds, Froude and Weber numbers, are well known[6-11]. In the following, the flotation cell will be treated as a baffled mixer; hence only the power number and the Reynolds number will be considered. To account for the effect of entrained air and suspended solids, air volume and pulp specific gravity are introduced, and the Power and Reynolds numbers are then defined respectively by:

$$N_p = \frac{Pg_c}{\rho N^3 d^5} \cdot \frac{1}{s(1-a)} \tag{1}$$

$$N_{Re} = \frac{\rho N d^2}{\eta} \cdot \frac{s(1-a)}{f_1 f_2} \tag{2}$$

Where P is net power (consumed power less transmission losses), g_c is the Newton's law conversion factor, d is impeller diameter, N is impeller rotational speed, ρ is density of fluid, η is viscosity of pure fluid, a is aeration volume, s is non-aerated pulp specific gravity, f_1 is a function of non-aerated pulp variables (ratio: non-aerated pulp viscosity/pure fluid viscosity), f_2 is a function of aerated pulp variables (ratio: aerated pulp viscosity/non-aerated pulp viscosity). f_1 and f_2 are still to be determined, though some aspects of the former have been investigated[12].

It is useful in equation (1) to replace d^3 by the cell volume, V, and to substitute power intensity Π for the term Pg_c/V. Also it will be noted that Nd is proportional to the linear peripheral speed πNd. So modified, equations (1) and (2) become:

$$N_p' = \frac{\Pi d}{\rho (Nd)^3} \cdot \frac{1}{s(1-a)} \tag{1a}$$

$$N_{Re} = \frac{\rho (Nd) d}{\eta} \cdot \frac{s(1-a)}{f_1 f_2} \tag{2a}$$

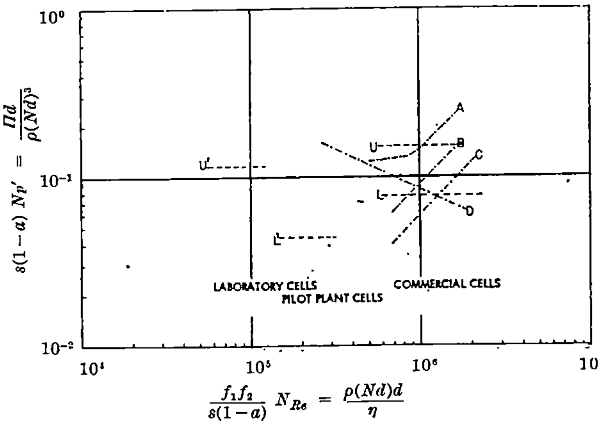

Fig. 1. Power factor – Reynolds number correlation for flotation cells

The literature is notably deficient in data for relating these dimensionless numbers. Without regard to the complex functions f_1 and f_2, there is little available on air entrainment volumes, and power figures where given at all usually are installed, rather than net values.

To make maximum use of the small amount of available data, attention was confined to Π, N and d. The constants for the fluid phase were ρ and η for water. With regard to the latter, Perry[6] suggests using the viscosity of the fluid phase when dealing with dispersions of gases in liquids; this is the procedure adopted here. Thus the groups become:

$$s(1-a)N_p' = \frac{\Pi d}{\rho (Nd)^3} \tag{3}$$

$$\frac{f_1 f_2}{s(1-a)} N_{Re} = \frac{\rho (Nd) d}{\eta} \tag{4}$$

Lines A, B, C and D (Fig. 1) are from approximate data supplied by four manufacturers. As in mixing, the radically different impeller design probably accounts for much of the difference in the relative positions of lines A, B and C.

The slope of unity for lines A, B and part of C follows from the scale-up criteria adopted, which (*a*) maintains constant peripheral speed for all cell sizes, and (*b*) estimates installed power from $\Pi \simeq$ constant. It will be noted from equations (3) and (4) that this is equivalent to plotting d against d. Line D is evidently based on different criteria. It is interesting to note that in baffled mixers N_p is almost independent of N_{Re} for $N_{Re} > 10^4$. Thus, in the absence of adequate mixer scale-up information (*b*) above is assumed, the value of Π being obtained from laboratory measurements, and for high Reynolds numbers N is calculated from $N_p \simeq$ constant[6,7,9].

Published and unpublished information for a range of commercial cells give values in the area enclosed by lines U and L. Estimated consumed power was used, and it is expected that net power values would be about 10 per cent lower. On the other hand, lines U' and L' enclose the area containing our own measurements on laboratory cells modelled after commercial cells, and here net power was used. Transmission losses for laboratory cells greatly exceed net power, and the use of consumed power would increase N_p about 10 times.

Thus, there is no reliable scale-up information between laboratory and commercial cells, or even for commercial cells alone.

In particular, the variation of peripheral speed and power intensity with cell size needs resolving. Once the relationships become established, they will provide a frame of reference for investigating the remaining operating variables. This should give an insight, for example, into the factors responsible for differences in the flotation-rate of the same material treated in different cells, both with regard to the size of cells and their design. In passing, it may be noted that this general correlation method should be applicable to the conditioning operation, which is likely to present fewer problems.

This possible correlation is brought to attention in the hope that adequate commercial data with which to establish this or some other correlation will now become available.

CHEMISTRY

Nomenclature of Silica

FOR many years the term 'fused quartz' has been used for describing vitreous silica prepared by the fusion of crushed quartz crystals. In some quarters the term 'vitreous silica' has been reserved for material made from an acid-washed sand, usually containing larger amounts of impurities. Unfortunately, the term 'fused quartz' is often abbreviated to 'quartz' in the later pages of a publication, and sometimes even in the title. A quick glance at *Chemical Abstracts* subject index for 1956 revealed four abstracts dealing with "quartz", where it was obvious that vitreous silica was meant[1]. The electrophoresis of "quartz particles in a quartz cell" is mentioned in one abstract. It is highly unlikely that the electrophoresis cell was of crystalline quartz; it was presumably vitreous silica. The question remains, were the particles also of vitreous silica? A recent example of the misnaming of silica is a paper dealing with vitreous silica and probably cristobalite[2] and headed "Whisker growth from quartz". It contains the sentence "The quartz substrate . . . had a skin of devitrified quartz . . . ".

The term 'amorphous silica' is not used in any more consistent fashion. In general, it denotes an artificial silica filler or a naturally occurring material such as opal or diatomite. The artificial silica powder, of submicroscopic particle size and correspondingly high specific surface, may have been prepared by one of two types of process. A material made from an aqueous soil by drying will readily take up moisture; the particles will be porous. Silica powders prepared by a condensation of SiO_2 or SiO from the vapour phase will be less hygroscopic. A material such as 'Fransil', consisting of tiny spheres of silica glass, might be better classified as a fine vitreous silica. Diatomite is comparatively coarse, but extremely porous. If it has been calcined, it will have been partly converted to cristobalite or even tridymite, both toxic materials.

The chemical and biological properties of the various forms of silica depend markedly on the polymorphic form (vitreous silica, cristobalite, tridymite, quartz, coesite), particle size, porosity, and thermal history of the surface, even when the material is very pure. The examples cited show that there is a need for greater care and detail in the description of various forms of silica by means of such terms.

Determination of Hydrogen in Gaseous Mixtures by Gas-Chromatography

IN the analysis of gaseous mixtures by gas-solid chromatography using hot-wire or thermistor detectors, it is usual to reduce the signal to the recorder, when necessary, by an attenuating system in the form of a potentiometric chain so that only a known proportion of the signal is applied to the recorder. This method results in the main components of a mixture being measured less accurately than impurities or components of small concentration. This is particularly true when hydrogen is a main component, as it has a thermal conductivity seven or eight times as great as most other gases or vapours, necessitating a large measure of attenuation to keep its peak on the chromatographic chart.

The gaseous mixtures commonly analysed in this Laboratory contain about 40 per cent hydrogen, and the volume of gas necessary to achieve sensible peak measurements for the nitrogen present results in a hydrogen signal from a katharometer bridge of about 115 mV. In the past this signal has been attenuated to about 2·3 mV. to allow the peak to be measured on the 3-mV. potentiometric recorder used. Thus 40 per cent of hydrogen is represented by 2·3 mV. or a deflexion of 214·5 mm., and an error of 1 mm. in measurement leads to an inaccuracy of about 0·5 per cent in the bridge signal.

It was therefore decided to reduce the signal to the recorder by applying an accurately determined e.m.f. in opposition to the output from the katharometer bridge. The conventional apparatus used had recorder sensitivities of 3, 5, 15, 25, 50 and 150 mV. for full-scale deflexion. Of these the 15 mV. range was selected as being the most practical one to use. On this scale, for a gas containing 40 per cent hydrogen an effective back e.m.f. of 105 mV. is required to keep the signal to a reasonable position on the chromatographic chart. This is achieved by applying an e.m.f. of 21 mV. (that is, 105 × 3/15 mV.) across the potentiometric chain in opposition to the signal to the recorder. The recorder then registers a peak from a signal of 10 mV., giving a deflexion of 186·4 mm. Thus an error of 1 mm. in measurement leads to an inaccuracy of only 0·05 per cent of the bridge signal.

This device was demonstrated by applying fixed signals from the katharometer bridge and noting that for each mV. applied from the test-box the expected decrease in recorder response was obtained. The device was then incorporated into new chromatographic units under construction and has since been used in the analysis of more than 200 gaseous mixtures containing hydrogen as a major component.

Heat Capacity and Resistivity Anomalies in Palladium Hydride

A recent paper on the electrical resistivity (ρ) of solutions of hydrogen in palladium[1] records maxima at 43° K. and 52° K. for the compositions (hydrogen/palladium) 0·60 and 0·54 respectively, whereas there is a linear fall of ρ when the hydrogen/palladium ratio is 0·48. A reproduction of the curves of ρ versus T by Schindler *et al.* is shown in Fig. 1. The maximum is evident in the graphs for the composition 0·60, but not for the composition 0·54; however, the authors state that for this composition there is a definite maximum in the points at the lower temperatures.

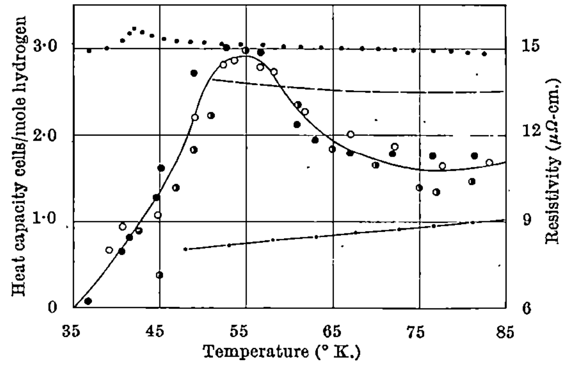

Fig. 1. Electrical resistivity and heat capacity per mole of hydrogen in certain solutions of hydrogen in palladium. ○, Cp H/Pd = 0·50 (Nace and Aston); ◑, Cp H/Pd = 0·25; ●, H/Pd = 0·125; ●●, ρH/Pd = 0·6; ——, ρH/Pd = 0·54; ●—●, ρH/Pd = 0·48

While the neutron diffraction work in ref. 2 leaves little doubt that there is hydrogen (hydrogen/palladium ~0·05) in the α-phase at room temperature, it is not unlikely that all the hydrogen is in the β-phase at lower temperatures.

Recent thermal studies in this laboratory have revealed slow exothermal processes on cooling solutions of hydrogen in polycrystalline palladium occurring near 150° K. and above 200° K. From the thermal drifts of the adiabatic calorimeter after various degrees of annealing, energies of activation of 6,400 and 2,900 calories were found for the upper and lower temperature processes respectively. In both cases graphs of the log of the rate of energy emission against $1/T$ gave good straight lines, except where annealing produced a state near equilibrium. This is in accord with anomalies in the heat capacity of hydrogen in palladium black (hydrogen/palladium = 0·50)[3] and one or both of these two processes may perhaps be thought of as connected with migration of hydrogens from the α- to the β-phase.

In view of the work on the resistivity[1] and of recent speculations concerning hysteresis in palladium hydride[4], heat capacity measurements for hydrogen in polycrystalline palladium with hydrogen/palladium ratios of 0·25 and 0·125 are of interest though perhaps not unexpected. The results, based on 1 mole of hydrogen in each solution, are given in Fig. 1 along with the earlier values for hydrogen/palladium equal to 0·50. The method used and the accuracy of the results are as given in ref. 3. Thus at hydrogen/palladium ratios of 0·125 and 0·25 the accuracy is respectively 2 per cent and 1 per cent of the heat capacity due to the hydrogen.

The heat-capacity maximum at 55° K. previously reported for a hydrogen/palladium ratio of 0·50 is not shifted at either composition and the results for both solutions lie on the same curve. The slow process occurring below 50° K. reported in ref. 3 was noted again. This is not connected with the two processes mentioned. By cooling the sample slowly through a temperature-range 30° above maximum, the slow process was 'annealed out' and all measurements were taken after this annealing.

The fact that the maximum is unchanged by composition at compositions of hydrogen/palladium below 0·50 might be taken to mean that all the hydrogen is in a phase of constant composition below room temperature. This would require migration of hydrogen from the α- to β-phase at low temperatures. However, if the hydrogen atoms are bound to palladium in such a way that there is little or no interaction between the protons, the heat capacities would not be affected very much by composition. This situation is unlikely. If the composition of the β-phase is constant, in view of the slow process occurring at the higher temperatures, it would seem that any process of ordering would most likely be one resulting in removal of some sort of rotational or librational process.

A comparison between the resistivity and heat-capacity data leaves little doubt that the maxima are connected. The results of Schindler *et al.*[1] indicate that the maximum in the resistivity curve may well be at 55° K. for a hydrogen/palladium ratio of 0·50. It is also not unlikely that the maximum in the heat-capacity curve would be shifted at higher concentrations of hydrogen. Heat capacities in this temperature-range at higher hydrogen concentrations will be studied.

Schindler *et al.*[1] suggest an anti-ferromagnetic transition as a possible cause of the maximum. The onset of rotational or re-orientation process used to explain the heat capacity maximum[3] would also produce an anomaly in g (ν) for the phonons and it is possible that the resistivity results might be explained on this basis. For compositions above Pd_2H it is not possible to connect the palladium atoms without bound hydrogen in endless chains[3].

'Gel Filtration' of Organic Compounds

Following Porath and Flodin's description[1] in 1959 of gel filtration as a fractionation method, it has been regularly used in this laboratory for separation of proteins and polysaccharides from sugar cane juice and sugar factory syrups. Unpublished results of the Swedish workers suggested that the method might be extended to the fractionation of substances in a narrow range of quite low molecular weights. Because of the possibilities of the method materials other than cross-linked dextran have been investigated here as alternative media for gel filtration.

In our laboratory Mountfort has shown that 'Dowex 50' cation-exchange resin (Na^+ form) gives partial fractionation of a mixture of mono-, di- and tri-saccharides in aqueous solution. Other workers have noted similar phenomena[2,3] and even a number of monosaccharides have been separated on 'Dowex 50' (Ba^{2+} form)[4]. As fractionation without the complications of ion exchange is often desirable, styrene-divinyl benzene copolymers, samples of which were obtained in bead form from the Dow Chemical Co., were tested. However, even with the least cross-linked resin, substances as widely different as egg albumin and glucose could not be separated in aqueous solution. Likewise, when alcohol was used as the liquid medium, no separation of such large and small organic molecules as eosin and formic acid could be achieved.

Meanwhile Vaughan[5] reported separation of polystyrene fractions in benzene on a cross-linked polystyrene which swelled to a very high degree in that solvent. He also suggested that fractionation of low molecular weight materials might be possible on less swollen resins, paralleling the separation of glucose from a dextran of number average molecular weight 1,000 by Porath and Flodin. We have now achieved the separation of several organic compounds using not only benzene but also a number of other liquids in which the resin swells to some extent.

The grades of copolymer available contained from 2–12 per cent divinyl benzene (DVB) and were designated *X*2, *X*4, *X*8 and *X*12. The swelling of each in a variety of solvents is shown in Table 1, being expressed as the ratio of swollen volume to dry volume (lightly packed).

Using columns of 1·4 cm. × 45–50 cm. and benzene as medium, almost complete separation of cholesterol and furfural was obtained with *X*2, *X*4 and *X*8 resins, but rather poor separation with the *X*12 resin. Cholesterol was eluted ahead of the furfural in each case.

Table 1. Swelling of Styrene – DVB Copolymers

Solvent	Swelling ratios (× 100) *X*2	*X*4	*X*8	*X*12
n-Butyl alcohol	105	—	—	—

'Shell *X*2' (100°)	165	130	105	100

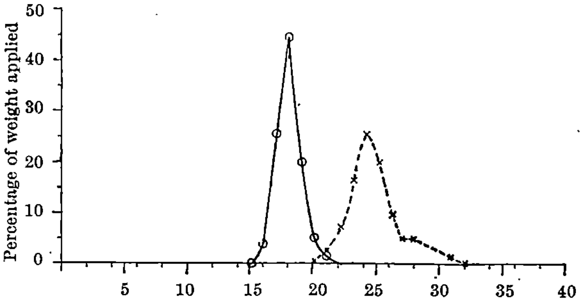

Fig. 1. Separation of resorcinol and 1-naphthylamine. ○, resorcinol; ×, 1-naphthylamine. Fraction volume, 5·1 ml.

With similar columns packed with *X*2 resin and using ethyl acetate or acetone, it was shown that it was possible to separate organic compounds with molecular weights in a much narrower range. Thus resorcinol and 1-naphthol (mol. wt. 110 and 144) when run separately in either solvent gave peak concentrations after different volumes of effluent and when run together were separated to a considerable extent. Resorcinol, although of smaller molecular weight, left the column ahead of the naphthol. Better separation of the two phenols was obtained in acetone than in ethyl acetate, although the resin swells less in acetone. By using a column 1·4 cm. × 140 cm. almost perfect separation of 0·4 gm. of each component was obtained.

To obtain quantitative data more readily, 1-naphthylamine was substituted for 1-naphthol. The phenol was determined by reaction with diazotized *p*-nitroaniline and the amine by its reaction with furfural in acetic acid. The separation of 0·1 gm. of each component in acetone solution is shown in Fig. 1.

Table 2. Effluent Volumes at Peak Concentrations

Substance	Molecular weight	Volume (ml.)
Acetaldehyde	44	165
Ethylamine	45	160
Ethanol	46	150
n-Pentanol	88	153
Furfural	96	167
Resorcinol	110	200
1-Naphthol	144	172
Alizarin	240	165
Quinalizarin	272	152
Cholesterol	387	126
Thymolphthalein	430	132

A number of compounds of varied structure were individually passed through a column 1·4 cm. × 135 cm. in benzene medium. The effluent volumes corresponding to peak concentrations of each were determined and are given in Table 2. The results suggest that gel filtration, as described by Porath and Flodin, is part of the mechanism involved in fractionation. However, the nature of each substance appears to be at least as important as its molecular weight. Thus, although cholesterol and thymolphthalein, both of high molecular weight, pass through the column ahead of the other compounds studied, a highly aromatic substance such as 1-naphthol will leave the column after aliphatic compounds of much lower molecular weight. In the aliphatic series the hydroxyl group causes relative exclusion (for example, compare ethanol and acetaldehyde). The extra hydroxyl group of resorcinol presumably explains its appearance ahead of 1-naphthol when these substances are run in acetone or ethyl acetate solution. In benzene solution resorcinol behaves differently and leaves the column a considerable time after such compounds as 1-naphthol and furfural.

In this case and with certain other substances, adsorption may play some part. When the benzene-soluble base from methylene blue was run through $X2$ resin, adsorption definitely appeared to occur, as there was a very large volume of effluent before the appearance of the dye, which was distributed in a much greater volume of solvent than usual.

The effect of the solvent is obviously great and the effect of the degree of cross-linkage of the resin is largely unknown. Much greater knowledge is required before a particular application or the optimum conditions can be predicted. However, the evidence suggests that here is a method which may assist in the isolation or purification of various natural or synthetic substances.

Structures of Polymeric Titanium Ethoxide and Titanium Oxide Ethoxides

RECENTLY, Martin and Winter[1] suggested two new structures for trimeric titanium (IV) alkoxides. Their suggestion that $Ti_3(OR)_{12}$ may involve 6-co-ordinated titanium in a trigonal prismatic rather than an octahedral configuration is interesting but a decision on this must await the results of X-ray diffraction analysis. Besides providing a more symmetrical structure for the trimeric titanium chloride tributoxide they claimed that the trigonal prismatic structure also alleviates certain difficulties concerning the structures we proposed[2] for the polymeric titanium oxide ethoxides, which were based on the octahedral trimer structural unit. There are two points at issue. First, they consider on mechanistic grounds that the formation of the trilinear polymer species $Ti_{3(x+1)}O_{4x}(OEt)_{4(x+3)}$ "requires statistically unfavourable mutual orientation of two $Ti_3(OR)_8(OH)_4$ units before effective collision and expulsion of four water molecules could occur, etc.". Secondly, they mention that our structure for $Ti_{3(x+1)}O_{4x}(OEt)_{4(x+3)}$ involves an unknown 4-covalent bonding arrangement between oxygen and its four nearest neighbours. Concerning the first point it must be emphasized that our structure was developed to account for the variation of the number average degree of polymerization as a function of the degree of hydrolysis for a whole series of titanium oxide ethoxides. The mechanism of the hydrolysis was not considered, it is indeed unknown, and it is of no significance provided that a rapid rearrangement of the initial hydrolysis products occurs, thus resulting in the formation of the most stable structure. Moreover, we reported evidence which suggested that disproportionation takes place and this involves rapid structural rearrangements between members of the polymer series:

for example,

$$6\,Ti_9O_8(OEt)_{20} \rightarrow Ti_3(OEt)_{12} + 2\,Ti_6O_4(OEt)_{16} + Ti_9O_8(OEt)_{20} + Ti_{12}O_{12}(OEt)_{24} + Ti_{18}O_{20}(OEt)_{32}$$

An important feature of our structural series was the fact that the number average degree of polymerization is independent of the distribution of polymer sizes (as can be verified by inspection of the above equation) and is determined exclusively by the average degree of hydrolysis. The alternative structures for $Ti_3(OR)_{12}$ proposed by Martin and Winter will not account for the variation of the number average degree of polymerization with degree of hydrolysis even if the postulation that the titanium oxide ethoxides contain some terminal Ti=O groups were true. Thus although the formulation $(RO)^t_4(RO)^b_6Ti_3(O)^b_2Ti_3(OR)^b_6(O)^t_2$, where $(RO)^t$, $(RO)^b$, $(O)^t$ and $(O)^b$ are terminal alkoxide, bridging alkoxide, terminal Ti=O and bridging TiO groups respectively, will account for the compound $Ti_6O_4(OEt)_{16}$ the logical development of such a scheme would predict species which are not members of the $Ti_{3(x+1)}O_{4x}(OEt)_{4(x+3)}$ series, including a limiting infinite polymer $[Ti_3O_3(OEt)_6]_\infty$. We now report some infra-red spectra (in carbon disulphide solution) of $Ti_6O_4(OEt)_{16}$ and $Ti_{12}O_{12}(OEt)_{24}$ in comparison with that of $Ti_3(OEt)_{12}$. Briefly stated, it appears that as the degree of hydrolysis is increased there is a decrease in intensity of the bands at or near 2,960, 2,900, 2,840, 2,680, 1,370, 1,350, 1,135, 1,102, 1,063, 1,038, 915 and 890 cm.$^{-1}$, which involve in various ways the ethoxide groups. Simultaneously there is an increase in intensity of bands at around 790 and 770 cm.$^{-1}$ which was absent in $Ti_3(OEt)_{12}$ and which must therefore be assigned to Ti·O·Ti systems. Hydroxyl bonds were not detected in these spectra, and this eliminates the possible presence of Ti—OH groups in the oxide ethoxides. According to Barraclough, Lewis and Nyholm[3] a strong band at 1,087 cm.$^{-1}$ was assigned to the Ti=O group in titanyl *bis*-acetyl acetonate while bands in the 800–900 cm.$^{-1}$ region in other 'titanyl' complexes were considered to be due to Ti·O·Ti·O·Ti· systems. Accordingly we conclude that the bands near 800 cm.$^{-1}$ in $Ti_6O_4(OEt)_{16}$ and $Ti_{12}O_{12}(OEt)_{24}$ must be due to oxygen bridges between titanium atoms and that these compounds do not contain the Ti=O bonds proposed by Martin and Winter. It is noteworthy that Zeitler and Brown[4] considered that bands at 820 and 763 cm.$^{-1}$ in titanium oxide *n*-butoxide were due to Ti·O·Ti bonds. Thus, the trigonal prismatic alternative configuration for 6-co-ordinated titanium does not appear to have any supporting evidence.

The second objection to our structure, namely, the unfamiliar configuration of the quaternary oxygen, is more difficult to answer. The oxygen is situated at the apex of a tetragonal pyramid with titanium atoms in the basal positions. We tried several alternative structures in attempts to produce a tetrahedral co-ordination of the quaternary oxygens but without success. However, examples can be cited in which other first-row elements (for example, beryllium, boron) exhibit co-ordination numbers which are "not allowed" according to simple valency theory. Wheatley[5] has shown by X-ray diffraction on LiOMe that the oxygen is pyramidally bonded to four lithiums in this compound, and this provides a precedent for our Ti_4O configuration. There seem to be two alternative explanations of the 'pyramidal' oxygen. First, if the four Ti—O bonds are covalent and equivalent then it is essential to invoke the participation of 3-centred and 5-centred molecular orbitals involving oxygen and two or four titaniums, respectively. The Ti_4O system would then involve only six of the eight valence electrons of the O^{2-}. The second possibility would require the Ti_4O group to be unsymmetrical with two Ti—O bonds being essentially covalent and considerably shorter than the other two, which would involve electrostatic attraction. It is relevant to note that the intermolecular bonds in $Ti_3(OEt)_{12}$ are fairly weak[6] while the infra-red-spectrum[7] does not appear to distinguish bridging ethoxide groups from terminal ethoxide groups. This could be taken as evidence that the intermolecular Ti—O bonds involve weak electrostatic binding. Preliminary results[8] on the high-resolution proton magnetic resonance of $Ti_3(OEt)_{12}$ in carbon disulphide at room temperature revealed only one type of ethoxide group. This suggests that the bridging and terminal ethoxide groups are exchanging positions extremely rapidly, and this reinforces our view that the hypothetical kinetic arguments of Martin and Winter are not relevant to the determination of the structures of titanium oxide ethoxides.

[8] Bains, M. S., Bradley, D. C., and Stothers, J. B. (unpublished results).

The preceding communication by Bradley and Westlake is most interesting, for it provides new experimental data in the form of infra-red spectra and high-resolution proton magnetic resonance measurements on the polymeric titanium (IV) ethoxide and titanium (IV) oxide ethoxides.

Contrary to their above statement, however, one of the several logical developments of our scheme does, in fact, predict species which are members of the $Ti_{3(x+1)}O_{4x}(OEt)_{4(x+3)}$ series suggested by the workers at Birkbeck College, namely:

$$Ti_3(OR)_{12}+Ti_3(OR)_6(OH)_6 \rightarrow Ti_6O_4(OR)_{16}+2ROH+2H_2O$$

$$Ti_6O_4(OR)_{16}+Ti_3(OR)_6(OH)_6 \rightarrow Ti_9O_8(OR)_{20}+2ROH+2H_2O$$

$$Ti_9O_8(OR)_{20}+Ti_3(OR)_6(OH)_6 \rightarrow Ti_{12}O_{12}(OR)_{24}+ +2ROH+2H_2O$$

However, it differs significantly from their linear model in that the limiting polymer would be finite rather than infinite, with the formula $Ti_{12}O_{12}(OEt)_{24}$ rather than $[Ti_3O_4(OEt)_4]_\infty$ (ref. 1). It may be relevant that the painstaking investigations of the group working at Birkbeck College have led to the isolation and characterization of only two members of their $Ti_{3(x+1)}O_{4x}(OEt)_{4(x+3)}$ series, namely $Ti_6O_4(OEt)_{16}$ and $Ti_{12}O_{12}(OEt)_{24}$, which suggests that these may be structures of special stability. No obvious points of stability are to be expected on their model, and, in fact, highly hydrolysed oxide-alkoxides with conjectural formulæ as high as $Ti_{75}O_{96}(OR)_{108}$ have already been invoked[2] in discussions of ebullioscopic data.

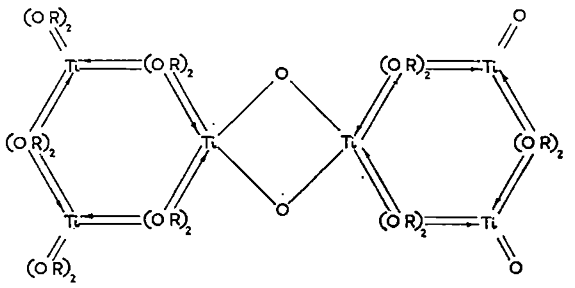

Fig. 1. $Ti_6O_4(OR)_{16}$

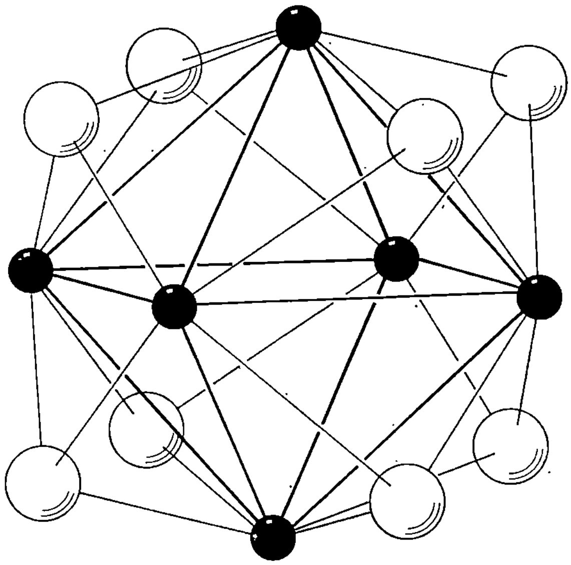

Fig. 2. Ti_6O_8 trisoctahedron

Structures for $Ti_6O_4(OEt)_{16}$ derived from a cyclic Ti_3-arrangement for the parent ethoxide, would also account very well for the observation[1,3] that on heating $Ti_6O_4(OEt)_{16}$ *in vacuo*, some $Ti(OEt)_4$ is recovered. This depolymerization could readily be initiated by the simple rupture of weak intermolecular bonds of the order of 5 kcal.[4,5] (see Figs. 1 and 2). That the ethoxy bridges are broken in this temperature-range is shown by the fact that *n*-alkyl-titanates are monomeric in the vapour state (for example, $Ti(OEt)_4$, b.p. 103° C. at 0·1 mm.)[4]. This depolymerization is rather more difficult to reconcile with the linear model for $Ti_6O_4(OR)_{16}$ (structure IV in our previous communication[6]), for each titanium atom is held in the structure by at least one strong covalent Ti—O—Ti bond, presumably of the order of 50–100 kcal. mole⁻¹, and a complete rearrangement would have to be postulated.

A further specific criticism made of our model is that it cannot accommodate the disproportionation scheme for oxide-alkoxide polymers. While we are not convinced of the occurrence of disproportionation in these compounds, Bradley and Westlake's criticism remains invalid, for numerical equations of the type illustrated here indicate that the number average degree of polymerization could also be independent of the distribution of polymer sizes for our model:

$$2[Ti_6O_4(OEt)_{16}] \rightarrow [Ti_3(OEt)_{12}]+[Ti_9O_8(OEt)_{20}]$$

$$3[Ti_6O_4(OEt)_{16}] \rightarrow 2(Ti_3(OEt)_{12}] + [Ti_{12}O_{12}(OEt)_{24}]$$

The case for disproportionation of $Ti_6O_4(OEt)_{16}$ was originally based on the time-independence of the number of osmotically active particles and the decrease in reactivity towards the Karl Fischer reagent which were observed on prolonged boiling in ethanol. Although Bradley, Gaze and Wardlaw[3] were unable to determine whether $Ti_6O_4(OEt)_{16}$ contained hydroxyl groups, they believed them to be absent, and therefore concluded that the reactive constituent must be bicovalent oxygen attached simply to titanium atoms, as in $\overset{\delta+}{\mathrm{Ti}}\text{—}\overset{\delta-}{\mathrm{O}}\text{—}\overset{\delta+}{\mathrm{Ti}}$. The decrease with time in Karl Fischer reactivity was then ascribed to progressive replacement of bicovalent by tricovalent oxygen as the molecular complexity of the oxide-alkoxide increased. This provisional interpretation has not been revised in terms of their subsequent $Ti_{3x+1)}O_{4x}(OEt)_{4(x+3)}$ model[1], and they have tacitly assumed that it continues to apply without modification.

It is not our purpose here to re-examine the case for disproportionation, but two comments will serve to illustrate that this thesis may be of doubtful validity. First, inspection of the linear model for $Ti_{3(x+1)}O_{4x}(OEt)_{4(x+3)}$ reveals that the number of bicovalent Ti—O—Ti groups (and of quaternary oxygen atoms) per titanium is, in fact, independent of molecular complexity, so that the decrease in reactivity to Karl Fischer reagent cannot be ascribed to this cause without either amending the original postulates or invoking long-range electronic effects. Secondly, the "apparent water content" of a crystalline sample of $Ti_6O_4(OEt)_{16}$ was found by them to decrease from 6·5 to 2·6 per cent simply by heating and recrystallizing the sample from ethanol (experiment *c*, ref. 3), so that the "active centres" cannot be the Ti—O—Ti groups as originally postulated.

With regard to the infra-red spectra reported by Bradley and Westlake, two points are at issue. First, we would agree with their conclusion that bands near 800 cm.$^{-1}$ in $Ti_6O_4(OEt)_{16}$ and $Ti_{12}O_{12}(OEt)_{24}$ must be assigned to oxygen bridges between titanium atoms. We direct attention again, however, to the unfamiliar configuration of the quaternary oxygen involved in the linear model, and stress that no simple Ti·O·Ti·O·Ti system is involved here. Examination of the alternative linear and cyclic structures for $Ti_6O_4(OEt)_{16}$ reveals that bonding of the type  occurs in both cases, and accordingly, their infra-red spectra in the 800 cm.$^{-1}$ region are unlikely to be dissimilar.

The second objection to our structure concerns the apparent absence of a Ti=O stretching frequency. Since the hydrolytic reaction scheme illustrated above represents only one of several possible schemes, the presence or absence of Ti=O groups in the hydrolysis products has little bearing on a decision between the linear and cyclic structures for the pure ester. For example, an attractive symmetrical close-packed $MoCl_2$-type structure can be envisaged for $Ti_6O_4(OEt)_{16}$ (Fig. 2), which does not involve terminal Ti=O groups. This structure, like our cyclic trimer, is again based on TiO_6-trigonal prisms with an octahedral skeleton of titanium atoms, with two terminal ethoxy groups attached to each. Each oxygen atom involved in the $Ti_6O_4(OEt)_4$-trisoctahedron is either 3- or 4-co-ordinated, in configurations, pyramidal or tetrahedral, both well established for oxygen.

In conclusion, we reiterate that the resolution of this polemic must ultimately await complete structure determinations of the ethoxide and two oxide-ethoxides, all of which can be obtained in crystalline form. Our original purpose remains, as stated previously, simply to direct attention to the fact that the linear model is by no means unique, and certainly, on the evidence available, does not yet enjoy the exclusive consideration claimed for it.

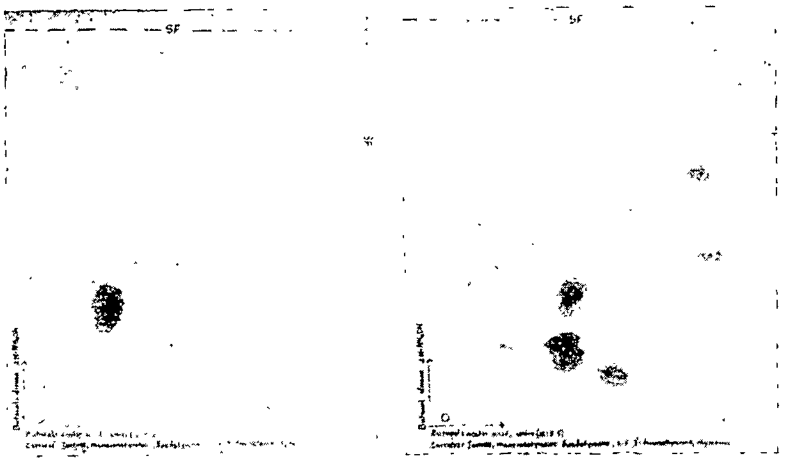
A Spray Method for the Simultaneous Detection of Iodide and Iodinated Amino-Acids on Filter Paper Chromatograms

For chromatographic identification of iodide and iodinated protein derivatives, it is often necessary to locate inorganic and organic iodide tracers on the same chromatogram. In paper chromatography a number of methods have been used for the detection of iodide. These include spraying with silver nitrate[1]; potassium chlorate, acid and starch[2]; 1 per cent aqueous palladium chloride[3]; a mixture of ferric nitrate and hydrogen peroxide[4]; the ceric-arsenite reagent[5]; and a mixture of $FeCl_3.6H_2O$, $K_3Fe(CN)_6$ and $NaAsO_2$ (*FFCA* reaction)[6]. Most of these tests for iodide interfere with those commonly used for the identification of iodinated amino-acids, namely, ninhydrin[7], diazotized sulphanilic acid[3], or its diethyl amide[8]. The ceric-arsenite and the *FFCA* reagents are the most sensitive (0·01 µgm. I$^-$) and can moreover be used for the detection of inorganic iodide, together with iodinated amino-acids on the same chromatogram[6,9]. The *FFCA* reagent, however, is not specific for iodine but also gives positive reactions with certain reducing substances[6]. The ceric-arsenite reaction has several disadvantages and is generally not used in the spraying technique[9].

The diazotized sulphanilic acid reagent can be used for the simultaneous identification of iodide as well as for iodinated amino-acids by spraying first with the diazotized sulphanilic acid, in which case a greyish or reddish-brown (depending on the concentration of iodide ions) spot locates iodide. This spot begins to disappear conveniently after 30 sec. and completely vanishes after about 2 min., thus leaving sufficient time for it to be marked. While the paper is still moist, 5 per cent (w/v) sodium carbonate is applied and the pinkish spots of the amino-acids appear. The iodine spots develop because of acid oxidation of iodide to iodine in the presence of sodium nitrite, since a mixture of 1·0 *N* hydrochloric acid and sodium nitrite, like sulphanilic acid and sodium nitrite (w/v), also give positive reactions with iodide. If the chromatogram is sprayed with sodium carbonate before it is sprayed with diazotized sulphanilic acid, the acid is neutralized and the iodine spots do not develop. In



a *b*

Fig. 1 (*a*) A two-dimensional chromatogram sprayed with diazotized sulphanilic acid to locate iodide. (*b*) The same chromatogram sprayed with 5 per cent sodium carbonate after the diazotized sulphanilic acid had been applied and the iodide spot had disappeared. Solvent systems: butanol/acetic acid/water (120 : 30 : 50) in one dimension; butanol/dioxan/2 *N* ammonium hydroxide (4 : 1 : 5) in the other dimension.
Carriers: 20 μgm. each of iodide, mono-iodotyrosine, diiodotyrosine, triiodothyronine, thyroxine

one- and two-dimensional chromatograms, quantities of 10 μgm. of iodide can still be easily detected by this method. Figs. 1*a* and *b* indicate the use of this test for the simultaneous identification of iodide and iodinated amino-acids.

BIOCHEMISTRY

Purine and Pyrimidine Metabolism in *Rhodospirillum rubrum*

WE have investigated the ability of the photosynthetic bacterium, *Rhodospirillum rubrum*, to deaminate aminopurines and aminopyrimidines.

Washed suspensions in 0·001 *M* phosphate buffer deaminate rapidly cytosine, methylcytosine and adenine to uracil, thymine and hypoxanthine, respectively. The products of the reaction were identified against authentic samples by paper chromatography with a variety of solvents, and the kinetics of the reaction followed either by eluting the spots and measuring the *E* values of the eluates at appropriate wave-lengths or, in the case of the adenine → hypoxanthine and cytosine → uracil conversions, by methods based on differential spectrophotometry. The method of Kalckar[1] was used for the first determination, and for the second determination we devised a similar method by which the amounts of cytosine and uracil could be determined by measuring ΔE at either 280 mμ or 250 mμ at *p*H 1·0. The production of 1 μmole of uracil per ml. of solution is indicated by a ΔE280 of $-$ 8·2 and a ΔE250 of + 3·74. The enzyme is soluble (not sedimented at 100,000*g* in cell-free extracts produced by sonic disintegration) with a sharp *p*H optimum for both pyrimidine and purine substrates at 7·0; it deaminates cytosine some ten times faster than adenine and about twice as fast as 5-methylcytosine. The chromatophores show no significant activity.

The specificity of the enzyme is indicated in Table 1. This shows that while guanine and *iso*guanine are probably deaminated to a very limited extent, neither 2,6-diaminopurine nor aza-adenine is attacked. Furthermore, aza-adenine does not inhibit deamination of adenine. With regard to pyrimidines, the specificity of the enzyme is more clear-cut; only those compounds carrying an amino group on position 6 are deaminated.

Table 1. SPECIFICITY OF THE PURINE/PYRIMIDINE DEAMINASE OF *Rhodospirillum rubrum*

Purines Compound	Activity	Pyrimidines Compound	Activity
Adenine	+	Cytosine	+
Guanine	?	5-Methylcytosine	+
*iso*Guanine	?	*iso*Cytosine	−
Aza-adenine	−	2-Aminopyrimidine	−
2,6-Diaminopurine	−	2,5-Diamino-4,6-dihydroxypyrimidine	−

Adenosine, when incubated with washed cells of *R. rubrum*, disappears rapidly ; no free inosine is ever detected, but after long incubation (over 4 hr.) traces of hypoxanthine are noted ; this suggests that adenosine is incorporated rapidly *in toto* into cellular material. Deoxyadenosine, on the other hand, is converted mainly into deoxyinosine ; small traces of hypoxanthine are observed after prolonged incubation. Cytidine was not attacked in any way ; deoxycytidine was not examined.

An attempt was made to demonstrate the presence of a deoxynucleoside transferase in *R. rubrum*. This enzyme will catalyse reactions similar to that recorded in (1). If such a reaction occurred, the adenine produced would be rapidly deaminated by the enzyme just discussed, while if it did not occur, the results of the reaction would be no different from the results observed with deoxyadenosine alone, that is, deoxyinosine would be the main product. Under our conditions, no deoxynucleoside transferase activity could be demonstrated in system (1), or when uracil was replaced by thymine and xanthine.

$$\text{deoxyadenosine} + \text{uracil} \rightleftharpoons \text{adenine} + \text{uracil deoxyriboside} \quad (1)$$

Hug and Werkman[3] found that whole cells and cell-free preparations of *R. rubrum* grown in darkness or light contain an active transaminase. In preliminary experiments in which adenine or cytosine were incubated with α-ketoglutarate we found that α-ketoglutarate had been aminated and adenine (or cytosine) had been deaminated. However, it soon emerged that this was not a new transaminase reaction, but that α-ketoglutarate was being aminated by the ammonium ions liberated during the deamination of adenine. Incubation of a washed suspension of *R. rubrum* with α-ketoglutarate and ammonium sulphate resulted in a marked formation of glutamate; under our conditions this was greater than when L-alanine was the amino donor.

It is hoped to publish this work in detail shortly. We thank the Royal Society for a grant to purchase a sonic disintegrator and Sigma Chemical Co. for a gift of purines and pyrimidines. This work was carried out in the Biochemistry Department, University of Liverpool. One of us (P. N. A. P.) carried out this work during the tenure of a Royal Thai Air Force scholarship.

Intracellular Glycosidases of Dextran-producing Bacteria

EXTENSIVE work on the mechanism of dextran production from sucrose by bacterial extracellular dextransucrase has not, so far, clearly established the identity of the initial acceptors involved *in vivo* in dextran chain initiation[1,2]. As a step to obtaining such information we have examined the intracellular glycosidase and transferase activities of two dextran-producing bacteria. These were *Leuconostoc mesenteroides* (NRRL *B*512, NCIB 8590; from the National Collection of Industrial Bacteria, Torry Research Station, Aberdeen) and *Streptococcus bovis* (strain I)[3].

Each organism was grown in an appropriate medium[3,4] containing sucrose (10 per cent w/v) plus sodium acetate (0·147 *M*). *Leuconostoc* cultures were incubated for 24 hr. at 25° and *Streptococcus* cultures for 5–6 hr. at 38°. During this time good growth occurred (*p*H fall from 7·0 to 5·8–6·0) but the dextran content remained sufficiently low to permit the cells to be collected easily. The centrifuged cells were washed twice in acetate buffer (0·05 *M*, *p*H 5·2) and disintegrated in 5–10 ml. of the same buffer at 2° in a Nossal cell-smasher[5]. After removal of cell debris by centrifugation the extracts were diluted with more buffer to give, from the cells from each litre of culture, 25 ml. of extract which was kept at 2° under toluene.

Digests were prepared containing cell-extract (0·25 ml.), buffer (0·25 ml., *Leuconostoc* extracts, acetate, 0·05 *M*, *p*H 5·2; *Streptococcus* extracts, phosphate–citrate, 0·15 *M*, *p*H 6·5) and sugar (10 mgm.). All sugars used were shown, by paper chromatography, to be pure or to contain only traces of sugar impurities. Controls omitting added sugar and cell-extract respectively were also prepared. The digests and controls were incubated for 24 hr. at 25° or 38° C. and analysed by paper chromatography, both before and after incubation, using ethyl acetate/water/pyridine (2 : 2 : 1) solvent and silver nitrate spray reagent[6].

The controls showed that neither the cell-extracts nor the added sugars alone produced any new sugars during incubation. Preliminary *iso*maltose, arbutin and sucrose digests, at various *p*H values, showed that the *Leuconostoc* carbohydrases were active over the *p*H-range 5·0–7·0, with maximum activity in the range 5·0–5·5, whereas the *Streptococcus* extracts were only active in the range 6·0–7·0, with maximum activity at about 6·5. The degree of hydrolysis of various sugars by the cell-extracts is shown in Table 1. In the disaccharide digests where strong hydrolysis occurred, there was also oligosaccharide formation by transferase action. *L. mesenteroides* was also grown in a 2 per cent maltose medium after passage through two maltose sub-cultures. The extract from these cells hydrolysed the same sugars as the sucrose cell-extracts at similar rates except for maltose, which was more rapidly attacked (spot-intensity of hydrolysis product + + +).

Table 1. HYDROLYSIS OF SUGARS BY EXTRACTS FROM DEXTRAN-PRODUCING CELLS OF *Leuconostoc mesenteroides* AND *Streptococcus bovis*

Sugar	Degree of hydrolysis*		
	L. mesenteroides extracts at *p*H 5·2		*S. bovis* extracts at *p*H 6·5
	25°	38°	38°
*iso*Maltose	+ + + + +	+ +	+ + + + +
*iso*Maltotriose	+ +	–	+ + + +
*iso*Maltulose	+		–
Melibiose	+ + +	–	+ + + +

Sophorose	+ + + +		–
Gentiobiose, lactose, cellobiose	–	–	–
Sucrose	+ + + + + +	+ + + + + +	+ + + + + +
Raffinose	–	–	+ + + + + +
Melezitose	–	–	–
Arbutin, salicin, æsculin, linamarin, lotaustralin	+ + + + + +	+ + + + + +	–
Amygdalin, hesperidin, rutin	–	–	–

* Degree of hydrolysis assessed visually from the spot intensity, on the chromatograms, of hydrolysis products on the scale: + + + + + +, intense spot with substrate completely hydrolysed; down to +, barely detectable spot, trace hydrolysis only and –, no hydrolysis. Blank space, not tested.

Strong invertase activity was present in all cell-extracts, although it is evident that the *Leuconostoc* invertase is much more specific with respect to substrate than the *Streptococcus* one. Chromatographic analyses of hydrolysates of small amounts of the isolated sugars suggest that the oligosaccharides produced in the cell extract-sucrose digests are the well-known fructosylsucrose trisaccharides normally produced by invertase action.

The only α-glucosidase present to any extent in the cell extracts of both bacteria was an apparently constitutive α-1,6-glucosidase. The presence of this enzyme, which hydrolyses the repeating unit of dextran (*iso*maltose), in two unrelated dextran-producing bacteria is striking. The β-glucosidase activity in the *Leuconostoc* extracts also seems unusual in that it was only able to hydrolyse the β-link in glucosides with monosaccharide and aglycone residues and did not attack disaccharide derivatives of this type. Further, apart from sophorose, it was without action on β-linked reducing disaccharides. Attempts are being made to separate purer fractions of the β-glucosidase and α-1,6-glucosidase from the cell extracts.

This work was initiated as part of a programme supported by the Department of Scientific and Industrial Research (United Kingdom) and completed in the Plant Chemistry Laboratories (New Zealand). Acknowledgments for the gifts of sugars are due to Dr. D. H. Hutson, Royal Holloway College (nigerose), and Dr. M. J. Clancy, Lister Institute (sophorose).

Isolation of Nigerose and Kojibiose from Dextrans

THE occurrence of 1,3-α linkage in some dextrans has already been suggested by many workers[1–5]. Barker *et al.*[3,4] have fractionated the partial acid hydrolysate of the dextran produced by *Betacoccus arabinosaseous* (Birmingham strain) on a charcoal column and recognized the presence of a trace of nigerose by paper chromatography. Jeanes *et al.*[5] have characterized dextrans from 96 strains of bacteria by periodate oxidation analysis and classified them into several groups on the basis of the proportions of 1,3 like linkages. According to their results, 29 of them appeared to contain more than 10 per cent 1,3-linkages and a few of them showed an extremely high content of 1,3-linkages (more than 30 per cent).

In 1956, Scott *et al.*[6] pointed out the presence of 1,2-linkage in some dextrans from the optical rotational shifts due to formation of a cuprammonium complex. According to their report, a few of them (for example, that from *Leuconostoc mesenteroides* NRRL *B*–1299 or *B*–1399) contain more than 30 per cent 1,2-linkages.

In spite of these observations, however, no oligo- or di-saccharides containing the heterogeneous glucosidic linkages have so far been isolated from the hydrolysates of dextrans. This may be due to the difference of the stability of 1,6- and other linkages against acid hydrolysis; the 1,6-linkage is much more stable than the other linkages. Therefore, by the usual method of hydrolysis in aqueous acid solution, heterogeneous linkages are more rapidly hydrolysed than the 1,6-linkage.

We have now found that acetolysis is more effective for the isolation of the heterogeneous linkages from dextrans. In contrast with hydrolysis, the 1,6-linkage is less stable to acetolysis, whereas the other linkages such as 1,2- and 1,3- are more resistant. For example, when the acetates of 1,6-linked isomaltose and 1,3-linked nigerose were subjected to acetolysis using the method to be described, the former was entirely cleaved into glucose in 6 hr. at 25° C., whereas the latter remained unchanged. By this method, we have now been able to isolate nigerose and kojibiose from the acetolysates of some dextrans. The dextrans used were prepared by the usual method from *Leuconostoc mesenteroides* NRRL *B*–421 and *B*–1299. The acetolysis reagent was a mixture of acetic anhydride, glacial acetic acid and concentrated sulphuric acid (24: 16: 3 by vol.). 20 gm. of dried and powdered dextran was suspended in 172 ml. of the above acetolysis reagent and kept at 30° C. for 7 days. The reaction mixture was then heated on a water-bath at 80° C. for 30 min. and poured into crushed ice. After neutralization with sodium carbonate, the whole solution was extracted with chloroform. On removal of the solvent, syrupy mixed acetates were obtained, which were deacetylated with sodium methoxide as usual. Yields of the acetolysates were 10–15 gm. from 20 gm. of the original dextrans. To ascertain if a reversible reaction had occurred, anhydrous glucose was treated exactly as described above; but no reversion product was detected by paper chromatography. The acetolysate of the dextran from *Leuconostoc mesenteroides* NRRL *B*–421 (29·7 gm.) was fractionated on a charcoal/'Celite' column by the gradient elution method. From the 5 per cent ethanol effluent, 7·8 gm. of nigerose and only 0·4 gm. of isomaltose were obtained. Nigerose was characterized as its crystalline octaacetate, melting point 149° C., undepressed on admixture with an authentic specimen.

In the same manner, 7·5 gm. of kojibiose and 1·0 gm. of nigerose were obtained from 22·0 gm. of the acetolysate of the dextran of *Leuconostoc mesenteroides* NRRL *B*–1299. Kojibiose was also characterized as its α- and β-octaacetates: α-kojibiose octaacetate, melting point 166° C.; β-kojibiose octaacetate, melting point 118° C. Neither acetates showed any depression on admixture with authentic specimens.

Thanks are due to Dr. F. R. Senti, of Northern Utilization Research Branch, Agricultural Research Service, U.S. Department of Agriculture (Peoria, Illinois, U.S.A.) for the gift of the strain of *Leuconostoc mesenteroides* NRRL *B*–1299.

Role of Lipid in the Hardening of the Cuticle in the Silkworm, *Bombyx mori*

Malek[1], and Dennell and Malek[2], have stated that the cuticle of *Periplaneta* becomes impregnated with a sterol and a protein rich in tyrosine, and Dennell[3] has given evidence that, in the development of the puparium of *Calliphora*, destruction of localized areas of the epidermis prevents the passage of sterol to the cuticle and also causes lack of tanning of the cuticle immediately above the operated areas.

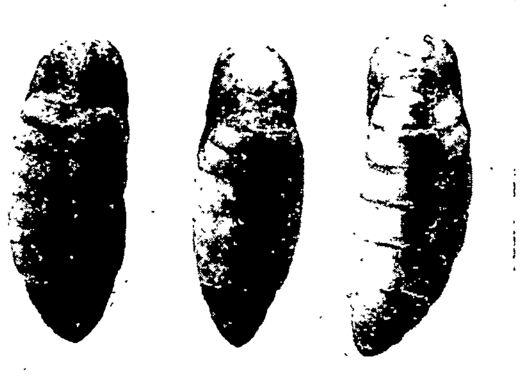
Table 1. HARDENING AND PIGMENTATION OF THE PUPAL CUTICLE TREATED WITH SOME ORGANIC SOLVENTS AT 25° C.

Solvent	Pigmentation	Hardening	Remarks
Methanol	(±)* ~ +	(±) ~ +	10–20 per cent of treated pupæ survived
Ethanol	(±) ~ +	(±) ~ +	,, ,,
Butanol	– ~ (±)	–	Died in a few hours
Acetone	(±) ~ +	(±) ~ +	10–20 per cent of treated pupæ survived
Ether	± ~ +	– ~ ±	Died in 2–3 days
Chloroform	– ~ (±)	–	Died in a few hours
Carbon tetrachloride	– ~ (±)	–	,, ,,
Benzol	– ~ (±)	–	,, ,,
Xylol	– ~ (±)	–	,, ,,
Ethyl acetate	– ~ (±)	–	,, ,,

* Brackets indicate that the effect was not usual. + = pigmentation (or hardening); ± = slight pigmentation (or hardening); – = no pigmentation (or hardening).

The lipid layer of the epicuticle of very young and soft pupæ of the silkworm *Bombyx mori* (race *N*124 × *C*124) has been removed within 30–150 min. of pupation either by immersion in ether for 10–15 sec. or by rubbing with cotton wetted with ether. After these treatments, pigmentation of the treated parts proceeds only slowly or imperfectly, and the cuticle remains unhardened. The pupæ thus treated shrank due to the evaporation of water, but some remained alive for a few days and showed an almost normal amber colour in the whole body or only in the region of the dorsal blood vessel (Fig. 1, *b* and *c*). This did not happen when methyl alcohol, ethyl alcohol, or acetone was substituted for ether. Pupæ treated with chloroform, xylol, benzene, ethyl acetate or carbon tetrachloride died within a few hours (Table 1).

Histochemical observation shows that the cuticle treated with ether is almost deprived of epicuticle lipid (see ref. 4). Replacement of the lipid by the ether extract from the cuticle or by 'Vaseline' prevented the pupæ from shrinking, but did not cause cuticle hardening to proceed.



(*a*) (*b*) (*c*)

Fig. 1. Pupæ 6 hr. after ether treatment. (*a*) Control; (*b*) and (*c*) treated pupæ

In agreement with Malek[1], and Jones and Sinclair[5], these results indicate that hardening and pigmentation of the cuticle are independent processes. However, it is not clear whether the lipid is directly involved in the hardening process, or whether it merely plays some part in facilitating the process. Microanalysis by paper chromatography has shown that the ether extracts from cuticles contain no phenolic substances.

I thank Prof. K. Hasegawa for his advice.

Action of Neuraminidase on Haptoglobin

IN the course of work on the chemical structure of haptoglobin (Hp)[1], we have had occasion to investigate the action of neuraminidase on the Hp and on the complex of Hp with hæmoglobin (Hb-Hp). The neuraminidase employed was prepared as described by Mayron and Rafelson[2,3] from influenza virus, Asian strain (Jap. 305), and is free of proteolytic activity and glucosidase activities other than neuraminidase action. The Hp II preparations utilized were prepared as previously described[4], and are considered to approach the stage of theoretical purity. Such preparations contain 5·1 ± 0·1 per cent N-acetylneuraminic acid (NANA)[1]. The liberation of NANA from Hp II and Hb-Hp II was determined by the method of Warren[5] using three-times crystallized NANA as a standard. A typical enzyme incubation at 37° employed 2–5 mgm. of Hp II or Hb-Hp II and 0·1 to 0·3 unit of neuraminidase in 0·1 *M* phosphate buffer, *p*H 6·5, total volume 2–3 ml. One unit of enzyme activity is defined as that amount of enzyme which liberates 1 mgm. of NANA from an excess of neuramin-lactose in 1 hr. at 37°, *p*H 6·5.

Fig. 1 shows the percentage of NANA liberated as a function of time from Hp II and Hb-Hp II by the

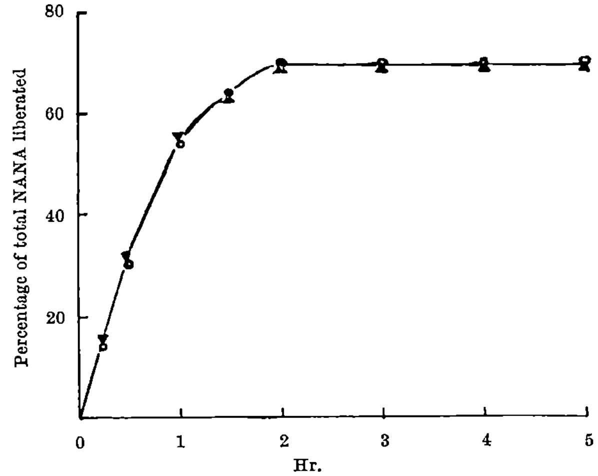

Fig. 1. Action of neuraminidase on Hp II and Hb-Hp. ○, Hp II; ▲, Hb–Hp II

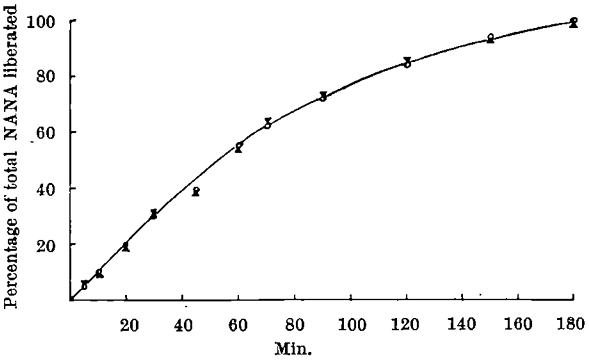

Fig. 2. Liberation of NANA from Hp 70 per cent NANA and from Hb–Hp 70 per cent NANA by 0·01 *N* hydrochloric acid at 80°. ○, Hp II 70 per cent NANA; ▲, Hb-Hp 70 per cent NANA

viral neuraminidase. It may be seen that the time-course of appearance of free NANA from the two substrates was identical, and that a maximum of 70 per cent of the total NANA was liberated in both cases. The *p*H optimum (*p*H 4·2) and the total peroxidase activity of the untreated complex (Hb-Hp), of the complex formed from untreated Hp II and of the complex formed from treated Hp (Hb-Hp 70 per cent NANA) were all identical. The conclusion which may be drawn from these results is that the 70 per cent of the NANA removed from Hp II and from Hb-Hp II participates neither in the formation of the Hb-Hp complex nor in the peroxidase activity of the complex. The possibility that the 30 per cent of NANA which is resistant to the action of neuraminidase may play a part in both the formation of the complex and in its peroxidase action cannot be excluded, although the following experiment suggests that this NANA is not involved in the formation of the Hb-Hp II complex.

Fig. 2 gives the results of an experiment in which the time-course of liberation of NANA by 0·01 *N* hydrochloric acid at 80° from Hp II previously treated with neuraminidase was compared with the liberation of NANA from the complex formed from this pretreated Hp II. The kinetic curves for the liberation of NANA from both substances were identical. These results are interpreted to suggest that the portion of NANA not liberated by the action of neuraminidase is not involved in the formation of the Hb-Hp II complex. If the 30 per cent of the NANA which is resistant to neuraminidase action were involved in the formation of the complex, it might be expected that kinetic differences in the release of NANA should have been observed.

Low-Angle Light Scattering and the Molecular Weight of Deoxyribonucleic Acid

It has been known for some time that the molecular weights obtained for deoxyribonucleic acid (DNA) by present-day techniques in light-scattering may be in error. This situation is not the result of theoretical barriers, but rather, the very considerable experimental problems to be solved in making reliable measurements of scattering below angles of 25°. Accordingly, considerable effort has been made to assess by indirect methods the validity of light-scattering molecular weights determined by extrapolation of data which extend to no lower than 25°. Doty, Geiduschek and Holtzer and more recently Butler *et al.* have given[1–3] detailed critical discussions of the nature of the indirect evidence and the remaining ambiguities.

In the case of molecules as large as DNA, measurements of light scattering must be made down to the angular region[1] of 6–10° to enable a reliable extrapolation to zero angle. Such measurements are necessary to determine the molecular weight of DNA and other very large macromolecules without appeal to any molecular models, but the experimental difficulties are so great that Doty has commented[1] that ". . . there is no likelihood of reaching this range [6–10°] because of practical difficulties".

The difficulties are, indeed, very great, but not insurmountable. I wish to report here measurements made on the scattering of a sample of calf-thymus DNA (prepared by a modification of the method of Signer and Schwander[4]) which sharply increase the likelihood of achieving reliable results at low angles. The measurements extend to 9°.

The scattering was measured in an instrument of my design the calibration and precision of which have been described[5] earlier. Its calibration constant determined by measurements on 'Ludox' is considered to be accurate to within a probable error of ± 0·3 per cent.

The results of the measurements are illustrated in Fig. 1. The plot has been made according to the equation :

$$\frac{Kc}{R_{\theta,u}} = \frac{1}{M_w}\left(1 + \frac{16\pi^2 n_0^2}{3\lambda_0^2}[\rho_G]^2 \sin^2(\theta/2) + \ldots\right) + 2A_2Q(\theta)c$$

where $R_{\theta,u}$ is the reduced intensity, c is the concentration (gm./ml.), K is $[2\pi^2 n^2(dn/dc)]/N_0\lambda_0^4$, M_w is the weight-average molecular weight, $[\rho_G]$ is the average radius of gyration, n is the refractive index of the solution and λ_0 is wave-length of the incident light *in vacuo* (here 4358 Å.).

The results can be fitted over the entire angular range of 9–45° by a straight line with a probable error of ± 4 per cent. Least-square calculations give $(Kc/R_{\theta,u})_{\theta=0} = 8\cdot2 \times 10^{-8}$ if all the data (9–45°) are included. The result is $7\cdot9 \times 10^{-8}$ when only the angular range 25–45° is considered and $8\cdot4 \times 10^{-8}$ for the range 9–17°.

The weight-average molecular weight obtained from the range 9–45° is $12\cdot2 \times 10^6$ and is independent of any assumptions concerning the shape. The

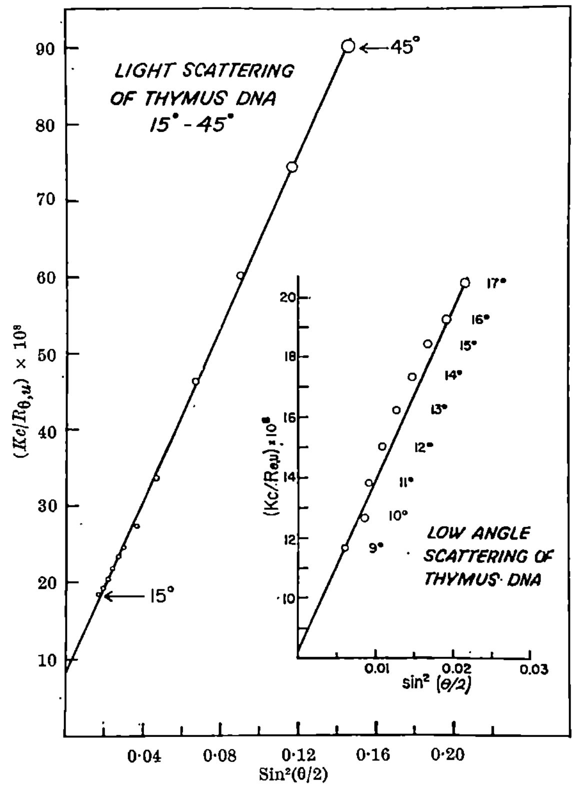

Fig. 1. The light-scattering of calf-thymus DNA in the angular region 9–45°. The straight line in both the main figure and the inset is that calculated by least squares for the entire angular region shown. The concentration of DNA was $3\cdot12 \times 10^{-5}$ gm./ml.

average radius of gyration, determined in the usual fashion, is 3700 Å. The reduced viscosity at zero shear for the sample reported on here was 45 as determined by measurements in a three-bulb viscometer.

The light-scattering data at higher angles, 50–135°, display a downward curvature which can be fitted reasonably well by a straight line in the range 60–135°. Extrapolated to zero angle, this line yields a value of 40×10^{-8} for the intercept. The interpretation[1–3] of the curvature is complicated: it may arise from polydispersity of molecular weights; it may be the result of variability in the shape of the molecules, nor is a combination of these two factors excluded. At present there is no unambiguous method of determining these properties independently for DNA in solution.

The experimental work reported here was completed at the Virus Laboratory of the University of California, Berkeley. It was supported partly by contract *NR* 121–175 between the Office of Naval Research and the University of California. A more detailed report of the experiments will be available shortly.

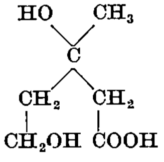
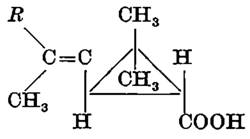
Biosynthesis of the Pyrethrins

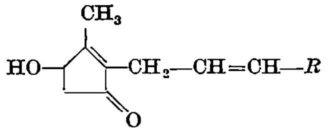
RECENT work[1] has indicated that mevalonic acid (I) is an intermediate in the biosynthesis of terpenoid compounds. We now wish to report some experiments which indicate that this acid is also involved in the biosynthesis of the 'pyrethrins', the insecticidal constituents of the pyrethrum plant, *Chrysanthemum cinerariaefolium*. The 'pyrethrins' are a mixture of four closely related esters[2] derived from two acids, chrysanthemum monocarboxylic acid (II, R = —Me) and pyrethric acid (II, R = —COOMe), and two keto-alcohols, pyrethrolone (III, R = —CH=CH$_2$) and cinerolone (III, R = —CH$_3$). It is customary to refer to the mixture of the two esters derived from chrysanthemum monocarboxylic acid and the keto-alcohols as 'pyrethrin I' and to that from pyrethric acid as 'pyrethrin II'. The two acids have carbon skeletons which can be built up from two isoprene units, and thus might be expected to be derived from mevalonic acid. The two keto-alcohols cannot be so regarded, but it is of interest to note that the methylpentenone ring could be formed in theory by the cyclization of mevalonic acid. We have now shown that this theoretically attractive route is not employed by the plant.



(I)



(II)



(III)

Because the pyrethrins are concentrated in the achenes[3] experiments on the incorporation of labelled compounds have been done on the flower head. Preliminary work with aqueous solutions of 2-^{14}C-acetic acid and DL-2-^{14}C-mevalonic acid showed that these two compounds moved slowly up the flower stem to the intact flower. A small amount of radioactivity was incorporated into the pyrethrins by this technique. A better incorporation was obtained by dropping an aqueous solution of the acid (I) containing a little detergent on the disk florets of the open flower. Finally, the highest incorporation was obtained by vacuum infiltration[4] of the substrate on ovules dissected from half-open flowers. This observation suggests that the pyrethrins are synthesized as well as stored in the achenes. It has also been found that the ovules from unopened and therefore unfertilized disk florets are slightly better at incorporating mevalonic acid into the pyrethrins than ovules from opened disk florets. This would seem to suggest, contrary to previous indications[5], that fertilization does not increase pyrethrin synthesis in the flower head.

The total pyrethrins were extracted from the plant tissue with acetone, and 'pyrethrins I and II' isolated by chromatography on silica gel/plaster of Paris[6]. The 2,4-dinitrophenylhydrazones of these compounds were prepared[7,8] and recrystallized to constant specific radioactivity. These derivatives were

[5] Bjorklund, R., and Katz, S., *J. Amer. Chem. Soc.*, **78**, 2122 (1956).

counted as thin films using an end-window counter. In a typical experiment DL-2-^{14}C-mevalonic acid (2 mgm., 2 μc.) was added to isolated ovules (2 gm.); after 24 hr. the incorporation of radioactivity into the pyrethrins had reached a maximum, corresponding to utilization of 1·4 per cent of the natural (+) isomer[9] of mevalonic acid. In a comparative experiment 2-^{14}C-acetic acid was incorporated to a much smaller extent, approximately one-tenth that of mevalonic acid.

Under strongly acid conditions in methanol 'pyrethrin II' yields with 2,4-dinitrophenylhydrazine the derivative of pyrethrolone methyl ether[7]. Using this method of splitting the esters in 'pyrethrin II', it has been found that while acetic acid is incorporated into the cyclopentenone ring, mevalonic acid is not. Thus, by difference, it is concluded that mevalonic acid is only incorporated into the terpene-like acids (II) of the pyrethrins. The exact location of the C-2 atom of mevalonic acid has not yet been determined; but it would seem very likely that it would be in the geminal methyl groups of the cyclopropane ring in both acids, and in a similar position in the isopropylidene group of 'pyrethrin I'. On the other hand, since the biosynthesis of the pentenones (III) does not involve mevalonic acid, it would seem to be either an example of the acetate route of biosynthesis that has been suggested by Birch and co-workers[10], or else to involve a precursor of mevalonic acid such as mevaldic acid[11] or 3-hydroxy-3-methyl-glutaric acid[12].

Conversion of L-Galactono-γ-lactone into L-Ascorbic Acid by Plants

It has been inferred from feeding-experiments that cress seedlings[1], and also pea and mung bean mitochondria[2], are capable of converting L-galactono-γ-lactone into L-ascorbic acid. Similar results were obtained with mitochondria from cabbage leaves and cauliflower florets, and a relatively specific L-galactono-γ-lactone dehydrogenase was isolated from the latter[3]. The results (Table 1) confirm that this system may not be uncommon in the higher plants; *Sphagnum*, *Spirogyra* and *Psalliota*‡ gave inconclusive results. The figures in Table 1 are either the mean of duplicate estimations, or are taken from single, extended experiments which show how the concentration of ascorbic acid in the tissue varies during the period of feeding. Fig. 1 shows the results of one such extended experiment with parsley, in which the concentration of ascorbic acid in the laminæ fed with the lactone rose, during a period of 190 hr., from 1,582 to 12,010 mgm./100 gm. dry weight, that is, to approximately 12 per cent of the dry weight. During the same period, the value for the controls in de-ionized water fell gradually to 1,120 mgm./100 gm. dry weight, and at this time the experimental laminæ possessed more than ten times the concentration of ascorbic acid in the controls.

Table 1. EFFECT OF FEEDING WITH L-GALACTONO-γ-LACTONE ON THE CONCENTRATION OF ASCORBIC ACID IN CERTAIN PLANT PARTS

* The tissue slices were suspended and aerated at 25° C. either in de-ionized water or in a 0·5 per cent (w/v) solution of L-galactono-γ-lactone.

† The petioles of the leaves (except for watercress) were stood either in de-ionized water or in the solution of the lactone. The watercress leaves were floated on the appropriate liquid in Petri dishes.

‡ North American material, kept during feeding in a constant-temperature room at a temperature of approximately 22° C. under a daily regime of 14 hr. light and 10 hr. darkness; light intensity approximately 500 ft.-candles. The remaining material was British and was kept during feeding on a window-bench in the normal laboratory, with a diurnal cycle of approximately 11 hr. light and 13 hr. darkness.

Three pathways have been proposed for the synthesis of ascorbic acid in plants: (i) from D-glucose via D-glucurono-γ-lactone[1]; (ii) from

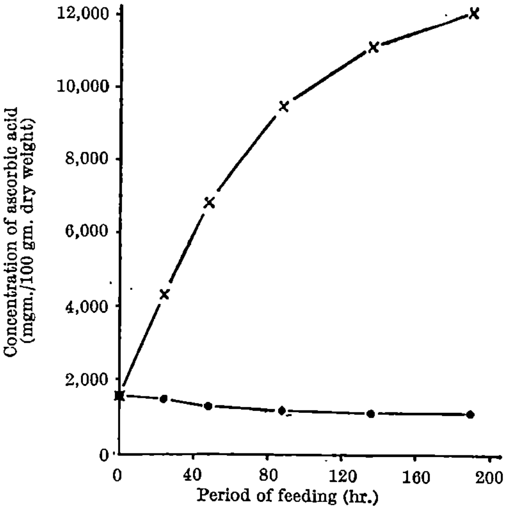

Fig. 1. Effect of feeding with L-galactono-γ-lactone on the concentration of ascorbic acid in the leaf laminæ of parsley†‡. ×, leaves with petioles standing in 0·5 per cent solution of lactone; ●, controls with petioles in de-ionized water

D-galactose via L-galactono-γ-lactone[1], and (iii) from D-glucose via glucose-6-phosphate and other phosphorylated intermediates[4]. Feeding with carbon-14-labelled compounds has led to the conclusion that, although D-glucurono-γ-lactone fed to strawberries may serve as a precursor in the synthesis of ascorbic acid[5], only pathway (iii) is involved in normal synthesis in this fruit and in cress seedlings[4,6]. On the basis of this view, any functional significance of the active system capable of converting L-galactono-γ-lactone into ascorbic acid remains to be elucidated; this problem is now being studied.

A Positive Feedback Mechanism of Adenosine Triphosphate Synthesis in Erythrocytes

IN previous papers, Nakao *et al.*[1,2] reported that adenosine triphosphate (ATP) is regenerated in erythrocytes stored for more than several weeks or treated with fluoride[3], when the cells are incubated with nucleoside and adenine at 37° C. In these aged or fluoride-treated cells, most of the nucleotides and other acid-soluble phosphate esters were decomposed almost completely and energy metabolism almost entirely stopped. To elucidate the mechanism of adenosine triphosphate synthesis in such erythrocytes, the following observations were carried out:

(1) As reported previously, inorganic phosphorus-32 (i^{32}P) and adenine-8-^{14}C were incorporated into ATP in long-stored erythrocytes after incubation with inosine, adenine-^{14}C and inorganic phosphorus-32. The incorporation of inorganic phosphorus-32 into ATP is inhibited by sodium-fluoride, mono-iodoacetate and arsenate, and adenine can be replaced by no other purine or pyrimidine bases, while inosine can be replaced by adenosine, deoxyadenosine, guanosine and deoxyguanosine though pyrimidine nucleosides were not effective[2]. These results show that ATP was synthesized from added adenine and added inorganic phosphate, and that glycolysis system and nucleoside phosphorylase seem to have some connexion with synthesis of ATP.

(2) The time-course of ATP generation during incubation with adenine and inosine in erythrocytes previously stored for 15 wk. or treated with sodium fluoride for several hours is shown in Fig. 1. The erythrocytes stored for 15 wk. or longer and those treated with sodium fluoride for 8 hr. showed a time-lag, in contrast to those stored for shorter periods or not treated with sodium fluoride.

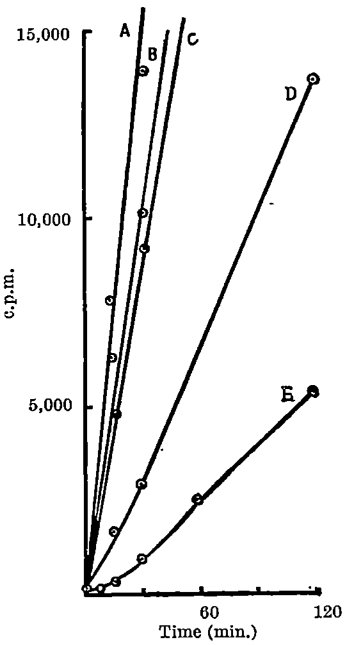

Fig. 1. Incorporation of adenine-8-^{14}C into nucleotide by intact erythrocytes. Reaction mixture contained 0·1 μmole (46·400 c.p.m.) of adenine-^{14}C, 5 μmoles of inosine, 0·7 ml. of intact cells, 2 μmoles of magnesium chloride, 10 μmoles of inorganic phosphate and 30 μmoles of *tris* buffer (*p*H 7·5); total volume, 1·32 ml.; temperature, 37° C. After incubation, the barium salt of nucleotides was isolated according to Kornberg (ref. 7) and its radioactivity was measured by means of a gas-flow counter. Pre-incubation with sodium fluoride of the blood stored for 4 wk. at 4° C. was carried out for 0(*A*), 2(*B*), 4(*C*), 8(*D*) hr. at 37° C. and (*E*) shows blood stored for 15 wk. at 4° C., in which no further pre-incubation was performed

(3) Hæmolysate obtained from fresh human erythrocytes was previously dialysed for 24 hr. at 4° C. and then passed through a 'Dowex 1' column in order to eliminate thoroughly all of the acid-soluble phosphorus compounds, using inorganic phosphorus-32 as an indicator. The incubation was carried out with a reaction mixture containing inorganic phosphate, magnesium, nicotinamide, adenine-8-^{14}C, either inosine or ribose-5-phosphate (R5P), and the pre-treated hæmolysate. When a trace amount of ATP was added to the medium, carbon-14 was found in adenosine monophosphate (AMP), but not in ATP, while no radioactivity was found either in AMP or in ATP, when ATP was not added to the reaction mixture. The time-course of the incorporation of adenine into nucleotide is illustrated in Fig. 2. It shows a remarkable increase in adenine-^{14}C incorporation with a time-lag in the case where diphosphopyridine nucleotide (DPN) was added and this time-lag disappeared when a greater amount of ATP was added to the medium. The results obtained from experiments (2) and (3) indicate that the existence of the lag phase was neither due to the inhibitory effect of a contaminating substance nor due to the induced

Table 1. SYNTHESIS OF ATP BY PRE-TREATED HÆMOLYSATE

Reaction mixture: Inosine, 50 μmoles, adenine, 5 μmoles, magnesium chloride, 10 μmoles, inorganic phosphate, 50 μmoles, DPN, 0·05 μmole, ATP, 0·05 μmole, nicotinamide, 66 μmoles, hæmolysate pre-treated as shown in the footnote of Fig. 2, 2·5 ml., total volume, 6·60 ml. Incubation was carried out for 60 min. at 37° C. After incubation, the acid-soluble fraction was analysed by Cohn and Carter's column chromatography on 'Dowex 1(*C*1)'

	Initial (μmole)	Final (μmole)	Difference (μmole)
Inosine	50·0	30·0	−20·0
Adenine	5·0	4·18	− 0·82
ATP	0·05	0·43	+ 0·38
ADP	–	0·51	+ 0·51
AMP	–	0·087	+ 0·087
Lactic acid	0	10·8	+10·8

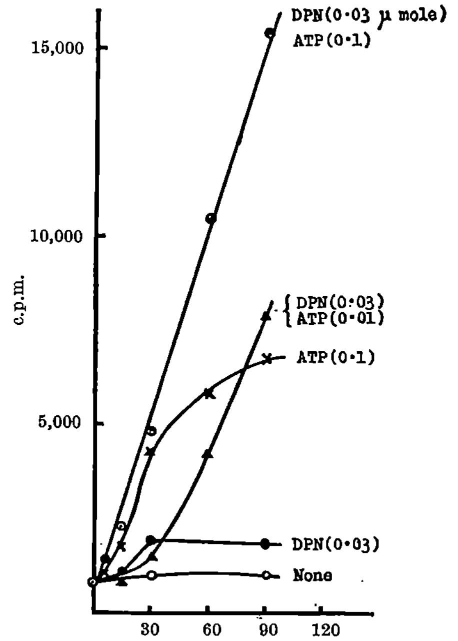

Fig. 2. Incorporation of adenine-8-^{14}C into adenine nucleotide by pre-treated hæmolysate. Reaction mixture contained 1 μmole (94·500 c.p.m.) adenine-8-^{14}C, 10 μmoles of inosine, 2 μmoles of magnesium chloride, 10 μmoles of inorganic phosphate, 10 μmoles of nicotinamide and 0·7 ml. of the pre-treated hæmolysate, namely, dialysed for 24 hr. at 4° C. and passed through 'Dowex 1' column (*Cl*) to eliminate thoroughly all the nucleotides, using inorganic phosphorus-32 as an indicator. The total volume was 1·32 ml. Incubation was carried out at 37° C.

formation of enzyme, but possibly due to the increase of coenzymes or of substrates.

(4) Not only incorporation of adenine-^{14}C into ATP, but also a net increase of ATP was determined by Cohn and Carter's ion-exchange chromatography[4] on 'Dowex 1', after the pre-treated hæmolysate was incubated with adenine, inosine, inorganic phosphate, magnesium, a small amount of DPN and of ATP, as shown in Table 1.

Preiss and Handler[5] reported in 1958 that R5P and ATP are converted to phosphoribosyl pyrophosphate (PRPP), and AMP and then PRPP and adenine yield AMP and inorganic pyrophosphate (PP) in acetone powder extract of human red cells. The presence of powerful adenylate kinase activity in human erythrocytes was reported by Tatibana *et al.*[6]. Moreover, there are a few observations indicating the existence of a considerable amount of glycolytic activity even in erythrocytes stored for more than several weeks. For example, when incubated with inosine, 2,3-diphosphoglyceric acid increased in erythrocytes stored for a long period[1,2] and lactate also increased in the erythrocytes when incubated with inosine and adenine or in hæmolysate when incubated with ATP and inosine. According to these results and the observations of others mentioned above, the mechanism of ATP generation might be explained tentatively as follows:

$$\mathrm{R5P} + \mathrm{ATP} \rightleftarrows \mathrm{AMP} + \mathrm{PRPP} \tag{1}$$

$$\mathrm{PRPP} + \text{adenine} \rightleftarrows \mathrm{AMP} + \mathrm{PP} \tag{2}$$

$$2\mathrm{AMP} + 2\mathrm{ATP} \rightleftarrows 4\mathrm{ADP} \tag{3}$$

$$4\mathrm{ADP} + n\mathrm{R5P} \rightarrow 4\mathrm{ATP} + X \tag{4}$$

(Warburg-Dickens system and Embden-Meyerhof system)

$$\text{Sum}: (n+1)\,\mathrm{R5P} + \text{adenine} + 3\mathrm{ATP} \rightarrow 4\mathrm{ATP} + \mathrm{PP} + X \tag{5}$$

The rapid formation of R5P from inosine and inorganic phosphate in erythrocytes or in hæmolysate is well established. R5P thus formed reacts with a trace amount of ATP still remaining in the cells, forming PRPP and AMP (1). ADP was synthesized from AMP, which was formed in both reactions (1) and (2), from remaining ATP, by the action of adenylate kinase (3). The ADP is converted to ATP in the course of R5P metabolism through Warburg–Dickens and glycolytic systems (4) (Fig. 3).

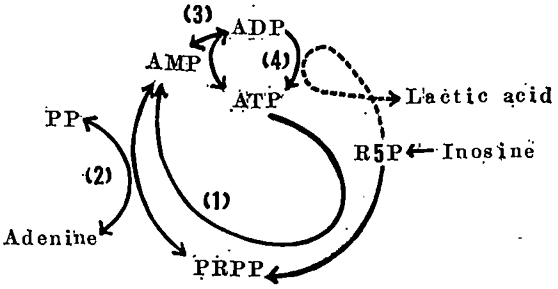

Fig. 3. A hypothesis of ATP regeneration in human erythrocytes

Thus, as a key substance, the trace amount of ATP remaining in the cells makes a cycle of reactions operative in synthesizing a greater amount of ATP; the further the reaction proceeds, the greater the increase in the amount of 'substrate ATP'.

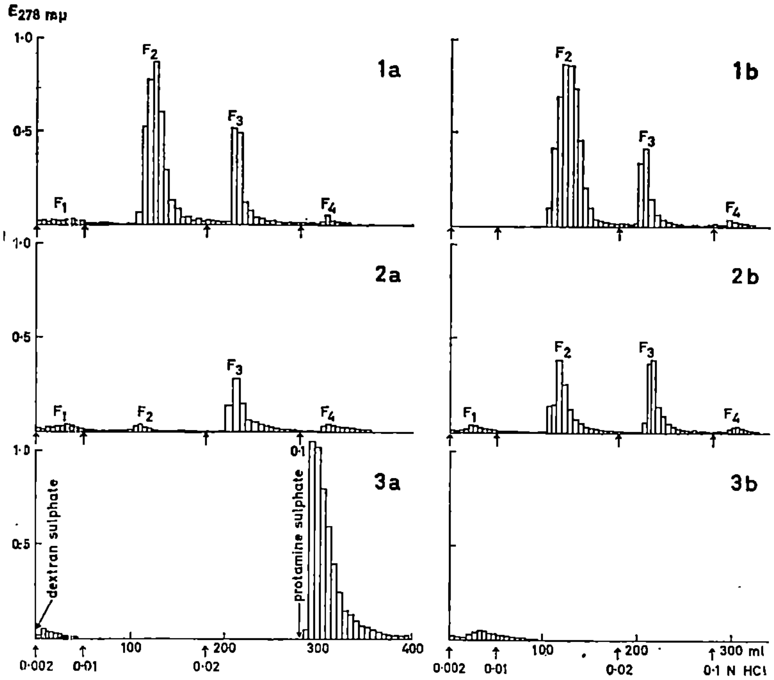
Influence of Polyvalent Ions on Histones isolated from Different Tissues

WHEN dealing with fractionation of histones, we observed that the chromatographic pattern became markedly different depending on the cellular origin of the preparation. We also found that these differences reflected the polysaccharide content of the tissue.

The technique was as follows: deoxynucleoprotein was prepared from fresh frozen tissue through precipitation with 0·15 *N* sodium chloride[1] and an extraction was made with 0·2 *N* hydrochloric acid[1]. The extract, which will contain histones as well as polysaccharides, was gel-filtered at + 4° C. on a 'Sephadex' column, *G* 25, with acetate buffer of *p*H 4·0



Figs. 1–3. Effluent diagrams of histones chromatographed on carboxymethylcellulose columns (15 cm. × 1·4 cm.). All the extracts were applied to the columns in acetate buffer, I = 0·02 and pH 4·0. Elution with hydrochloric acid of the concentrations marked on the horizontal axis. 1*a*, Run of histones from chicken erythrocytes; 1*b*, the same run as 1*a*, but with protamine sulphate added to the extract before the application to the column; 2*a* and 2*b*, the corresponding runs of histones from calf liver; 3*a*, run of calf thymus histones to which has been added an equivalent amount of dextran sulphate before the extract has been added to the column. Thereafter elution with protamine sulphate. 3*b*, run of protamine sulphate (salmine) alone (from Nutritional Biochemicals Corporation)

and an ion-strength of 0·02 [2,3]. For separation of histone fractions, chromatography on carboxymethylcellulose (CMC) was utilized[4]. The stepwise elution was made with 0·002 N, 0·01 N, 0·02 N and 0·1 N hydrochloric acid. The elution was followed through measurements of the extraction at 278 mμ.

Fig. 1*a* shows the chromatographic pattern of extract from chicken erythrocytes during the stepwise elution of the CMC-column. Two distinct and homogeneous fractions of histone were obtained, the peaks F_2 and F_3. Almost the same pattern appeared with extracts from thymus of calf, pig and lamb and from lymph nodules of calf. The ratio F_2/F_3 shows only a slight variation within this material. All these tissues can be regarded as containing a high proportion of histones in relation to polysaccharides. The main difference between the two histone fractions, which are eluted with different strengths of the acid, should be that F_3 is a more basic protein than F_2. Besides, with reference to end-group analyses[4], F_2 and F_3 may represent two qualitatively different types of histones. Fig. 2*a* demonstrates the corresponding elution pattern from calf liver. In this case the histone fraction F_2 is almost non-existent. The same very low ratio F_2/F_3 was also obtained with extracts from other kinds of liver—pig, mouse and chicken—and from whole chicken embryos. All these tissues should have a relatively high amount of polysaccharides in relation to histones. The pattern from extract of calf white blood corpuscles certainly showed both F_2 and F_3, but the ratio F_2/F_3 was low and intermediate between the two groups.

To demonstrate that it was the polysaccharides, which interfered with the histone fractions, an equivalent amount of the acid polysaccharide dextran sulphate was added to thymus-histone attached to the CMC-column. Thereafter no histone could be obtained during the subsequent elution, because the formed histone-polysaccharide complex was not dissociated at the low hydrogen ion concentrations used, Fig. 3*a*. If thereafter an equivalent amount of protamine sulphate was added to the column, the less basic histone is replaced by the more strongly basic protamine in the polysaccharide-complex and the histones can now be eluted quantitatively (Fig. 3*a*). Fig. 3*b* demonstrates the simple chromatographic pattern with protamine alone, which shows that protamine will not interfere with the absorption peaks at 278 mμ of the histone fractions. Figs. 1*b* and 2*b* show the chromatographic pattern after addition of protamine to the histone extract from the two tissues exemplified here. The amount of the F_2-histone has increased, most highly from the polysaccharide-rich extract, 2*b*, while the change in amount of the F_3-histone is only slight. Entirely corresponding results were obtained with the other tissues examined. Thus the F_2-histone has obviously much greater affinity for acid polysaccharides than the F_3-histone.

Thus it seems clear that a quantitative analysis of the native DNA-histone relation cannot be made without a blockading of other acid polyvalent ions, especially of polysaccharide type, and it seems likely that also in the living cell there is the same competition for histones between nucleic acids and acid polysaccharides.

Side-Reactions during Hydrogenolysis of 2,4-Dinitrophenylhydrazones of Aromatic Keto-Acids

The identification of the keto-acid 2,4-dinitrophenylhydrazones is greatly facilitated by conversion to their respective amino-acids. The most commonly employed procedure is that first noted by Emil Fischer[1] and modified for application to organic systems by Towers *et al.*[2]. This involves low-pressure hydrogenolysis over a platinum catalyst, followed by paper chromatography of the amino-acids produced. The yields of the respective amino-acids vary between 30 and 98 per cent, and in general the conversion is free from side-reactions.

However, the hydrazones of the dicarboxylic acids, α-ketoglutaric and oxalacetic acids, may undergo some decarboxylation during this reaction. Thus, small quantities of alanine are produced from oxalacetic acid, and both α- and γ-aminobutyric acids, in addition to the expected glutamic acid, are found after hydrogenolysis of the 2,4-dinitrophenylhydrazone of α-ketoglutaric acid[2,3].

During recent work on the keto-acid excretion in phenylketonuria and tyrosinosis[4] another potentially important deviation from the theoretical keto→ amino-acid conversion could be demonstrated.

Hydrogenolysis of the 2,4-dinitrophenylhydrazone of phenylpyruvic acid employing the conditions recommended by Towers *et al.*[2], namely, a 12-hr. hydrogenation in distilled water at 25° C., using 30 lb./in.^{2} pressure, and 0·2 gm. of platinum oxide catalyst, yielded a mixture of two amino-acids. The main product was phenylalanine, but sizeable amounts of a non-aromatic substance with chromatographic properties of cyclohexylalanine could also be found (Table 1).

Table 1. CHROMATOGRAPHIC BEHAVIOUR OF HYDROGENATION PRODUCTS OF KETO-ACID 2,4-DINITROPHENYLHYDRAZONES

Keto-acid 2,4-dinitrophenylhydrazone	R_F of hydrogenation products			Relative intensity	Amino-acid formed
	1*	2†	3‡		
Phenylpyruvic acid	0·56	0·37	0·82	3+	Phenylalanine
	0·74	0·53	0·84	1+	Cyclohexylalanine
p-Hydroxyphenylpyruvic acid	0·39	0·28	0·64	Trace	Tyrosine
	0·37	0·32	0·84	1+	Hexahydrotyrosine
	0·73	0·55	0·84	2+	Cyclohexylalanine

Descending chromatography. No. 40 Whatman paper.

* Solvent 1: *n*-butanol (120 parts); glacial acetic acid (30 parts) water (50 parts).

† Solvent 2: 95 per cent ethanol (180 parts); water (10 parts); concentrated ammonium hydroxide (10 parts).

‡ Solvent 3: Liquid phenol (200 parts); concentrated ammonium hydroxide (1 part).

Spots identified by spraying with a 0·2 per cent solution of ninhydrin in acetone containing 2 per cent pyridine.

The chromatographic behaviour of the products was compared with cyclohexylalanine and hexahydrotyrosine prepared according to Waser and Brauchli (ref. 6).

When the 2,4-dinitrophenylhydrazone of *p*-hydroxyphenylpyruvic acid was hydrogenated under similar conditions, approximately equal amounts of hexahydrotyrosine (4-hydroxycyclohexylalanine) and cyclohexylalanine were obtained. Tyrosine, the expected product, was only present in small amounts (Table 1).

The production of the hydrogenated derivatives of phenylalanine and tyrosine represent an unwelcome side-reaction, which, however, is not unexpected.

Many workers have shown that under the conditions employed for hydrogenolysis of the keto-acid 2,4-dinitrophenylhydrazones, hydrogenation of the aromatic ring can also occur. The rate of hydrogenation of the ring has been found to be first order with respect to hydrogen pressure, zero order with respect to the concentration of the compound to be hydrogenated, and directly proportional to the amount of catalyst used[5]. Thus, under the very conditions used in my experiment, hydrogenation of phenylacetic acid proceeds rapidly, 50 per cent of the starting material being converted to cyclohexylacetic acid within 60 min.[5].

Cleavage of the phenolic group has also been described. Waser and Brauchli[6], in subjecting tyrosine to low-pressure hydrogenation over platinum, obtained a mixture of hexahydrotyrosine and cyclohexylalanine.

Factors favouring the replacement of the phenolic group by hydrogen are hydrogenation in an acidic medium[7], relatively low pressures, and a symmetrical structure for the substance to be hydrogenated[8]. Thus, *para*-substitution favours the replacement of OH-groups, while *ortho*-substitution retards it[9].

In concluding, it must be emphasized that side-reactions such as those reported in this communication do not detract from the usefulness of the hydrogenolysis of the α-keto-acid 2,4-dinitrophenylhydrazones as a step towards their identification.

PHYSIOLOGY

Function of Taste Fibres in the Carp

THE carp (*Cyprinus carpio* L.) has a palatal organ supplied by nerve fibres running into the glossopharyngeal nerve. By dissecting and isolating small strands of the nerve branches running to the palate, it has been possible to obtain records of the electric response to the application of different sapid solutions to the mucous surface of the palatal organ.

It was found that such nerve preparations responded to a variety of test solutions such as 0·5 *M* sodium chloride, 0·005 *M* acetic acid, 0·01 *M* quinine and 0·5 *M* sucrose. These nerve preparations also responded very strongly to human saliva, as well as to the mucin covering the scales of the fish. The integrated response of such a nerve-strand to human saliva was generally quite as big as the response to 0·5 *M* sucrose and considerably greater than the response to 0·5 *M* sodium chloride.

A study of single fibre responses revealed that the saliva always stimulated fibres which responded positively to sugar. Fibres which responded to sodium chloride and acid or to quinine, but not to sugar, did not respond to human saliva, but for two exceptional cases. According to their response pattern the palatal chemoceptive fibres seem to be divided into six groups as will be seen from Table 1. Among these different fibres the types I, II and III are most common. So far we have only encountered two fibres of type VI.

Besides chemoceptive fibres and motor fibres, the palatal nerves contain fibres which respond very selectively to mechanical stimulation. The number of such fibres seems, however, to be relatively small

Table 1

Fibre type	Sodium chloride	Acetic acid	Quinine	Sucrose	Saliva
I	+	+	−	+	+
II	+	+	+	+	+
III	−	+	−	+	+
IV	+	(+)	−	−	−
V	−	+	+	−	−
VI	−	+	−	−	+

compared with the chemoceptive fibres. A comparison of the chemoceptive response of the palatal nerves with that from the nerves innervating the lips, the barbels and the gill rakers gives us the impression that the palatal nerves are the most important taste nerves of this species.

That human saliva is such a powerful stimulant of the palatal organ gives us, of course, a certain aspect on the angler's habit of spitting on the bait.

Pharmacology of the Alkaloidal Fraction from the Bark of the Jamaican Shade Tree *Pithecolobium samath* Benth.

A PHARMACOLOGICAL screening programme of extracts of plants used as folk medicines in Jamaica for the preparation of the so-called 'bush teas' is being carried out in collaboration with a group under Prof. L. J. Haynes at the Department of Chemistry, and with Dr. P. C. Feng at the Department of Physiology, University College of the West Indies, Jamaica. The shade tree, *Pithecolobium samath* Benth., was selected for detailed study. The main alkaloid from its bark, pithecolobine, had already been isolated by Wiesner *et al.*[1], who have given its partial structure[2].

A crude alkaloidal fraction was isolated from the powdered bark of the shade tree by extraction with dilute hydrochloric acid. The extract was made alkaline and then washed with chloroform, and these washings were then extracted with dilute hydrochloric acid. The acid extract was made alkaline and re-extracted with chloroform. The chloroform was evaporated to give an oil. Paper chromatography of this oil in several solvent systems showed one major component, presumably identical to pithecolobine, and only traces of a second component were disclosed with Dragendorf's reagent[3].

This fraction (referred to as pithecolobine) when injected intraperitoneally into mice (40 γgm./gm. body-weight, *BALB/C* × *C*57 mice) produced characteristic convulsions within 2–4 min. The stages were: first hypersensitivity to auditory stimuli, followed by muscular twitching and vertical head tremor, clonus first appeared in the hind limbs and then became more generalized with jumping. Between convulsions the animal appeared flaccid with apparent paralysis of the fore and hind limbs. Clonic attacks were followed by rapid respiration, gasping, exophthalmos and death. With lower doses the severe clonic attacks did not occur and surviving animals were subdued for up to 90 min.

The LD_{50} at room temperature (20°) for pithecolobine injected intraperitoneally was 40 γgm./gm. body-weight, the LD_{50} was approximately halved at both 4° and at 36°. Doses of 12 γgm./gm. body-weight of pithecolobine reduced the quinalbarbitone sleeping time of mice by 20 per cent; higher doses (12–18 γgm./gm. body-weight) increased it by up to 100 per cent. The toxicity of pithecolobine for mice was approximately doubled by the doses of quinalbarbitone (450 γgm./gm. body-weight) used for sleeping-time determination. When mice were given pithecolobine intraperitoneally (14 γgm./gm. body-weight) the rectal temperature, normally 37° C., dropped to 33° C.; when given quinalbarbitone alone it dropped to 29° C. and when given both it dropped to 26° C. Intravenous pithecolobine reduced the arterial blood pressure in the anæsthetized cat (4 mgm./kgm.) and rat (1·5 mgm./kgm.) by about 20 per cent for 5 min., both before and after vagotomy. In the anæsthetized rat, hypotensive doses of pithecolobine caused a marked increase in the amplitude and decrease in the rate of respiration. Perfusion of the spinal cord of the frog[4] with pithecolobine (15 γgm./ml.) reduced or abolished the electrically stimulated reflex contractions of the femoral biceps.

The most striking peripheral effect of pithecolobine is its local anæsthetic activity. It is apparently twice as potent as cocaine in the frog lumbar plexus test for local anæsthetics[5]. The intradermal weal test on guinea pigs[5] showed that injection of 1–3 mgm. of pithecolobine caused local anæsthesia for up to 8 hr. Similar results have been obtained in man. Pithecolobine did not produce significant corneal anæsthesia[6] in guinea pigs or rabbits. Pithecolobine appeared to have a generalized depressant effect on isolated organ preparations; for example, on the electrically stimulated phrenic nerve diaphragm[7], on the contractions of the guinea pig ileum induced by acetylcholine, histamine, nicotine and barium, on the contractions of the rat fundus strip induced by 5-hydroxytryptamine[8], and on the Langendorff preparation of the isolated rabbit heart.

The nature of the convulsions caused by pithecolobine and its effects on respiration, sleeping-time, and possibly temperature, suggest that this substance has some action on the brain stem. These pharmacological actions of pithecolobine are of particular interest because of the very unusual structure[2] of this alkaloid. Chemical studies of the alkaloids of the shade tree are under way at the University College of the West Indies and we hope to investigate fully both the pharmacology and biochemistry of pure alkaloids from this source.

We wish to thank Prof. A. C. Frazer for his interest and encouragement, and Dr. R. Schneider, Dr. M. R. A. Chance and Dr. K. Sargeant for valuable advice and help. This investigation was supported by the Tropical Products Institute, Department of Scientific and Industrial Research.

Note added in proof. Further work suggests that the local anæsthesia produced by intradermal injections of pithecolobine is due to damage to nerve endings.

Urea Synthesis in the Living Rat Brain

In previous communications from this laboratory, the synthesis of urea-^{14}C from arginine-^{14}C was reported to occur in the living rat brain[1,2]. In these experiments only the rat brains were analysed for their radioactive urea content, and the objection was raised that perhaps these levels did not indicate endogenous brain urea synthesis, but were merely a reflexion of blood ^{14}C-urea levels, especially since it is known that urea readily diffuses across the blood brain barrier. Experiments were therefore designed to show that the brain ^{14}C-urea levels were independent of blood ^{14}C-urea levels and that the brain had the capacity to synthesize urea from arginine. This communication describes such experiments.

Guanido-^{14}C labelled L-arginine-hydrochloric acid was obtained through the courtesy of the California Corporation for Biochemical Research before it was commercially available and was further purified by descending paper chromatography in two consecutive solvent systems. Solvent 1: pyridine/acetic acid/water (50 : 35 : 15). Solvent 2: ethanol/water/diethylamine (76 : 23 : 1). Identification was determined using the ninhydrin spray[3], and a modification of the Sakaguchi test[4] in conjunction with coincidence of radioautography. The R_F of the arginine in the above two solvent systems was 0·40 and 0·46 respectively. The purity of the arginine-^{14}C was verified by chromatography of the arginine eluate from the second solvent system in separate solvent systems of 2,6-lutidine/collidine/water/diethylamine (1 : 1 : 1 : 2 per cent v/v), propanol/acetic acid/water (75 : 5 : 20) and 2,4-lutidine/collidine/water/diethylamine (1 : 1 : 1 : 2 per cent v/v), propanol/acetic acid/water (75 : 5 : 20) and 2,4-lutidine/collidine/acetic acid/water (1 : 1 : 5 per cent v/v : 2).

A 90-day-old male albino rat (Sprague–Dawley strain) was lightly anæsthetized with diethyl ether and the exposed saphenous vein was cannulated with a heparinized, polyethylene cannula. 5 min. later an intracisternal injection of 0·4 mgm. of guanido-^{14}C labelled L-arginine-hydrochloric acid was administered using a micro-calibrated syringe (total activity 10 μc. = 7·3 × 10^6 counts/min.). At intervals following the injection, 0·5 ml. samples of blood were withdrawn from the vein and analysed for the specific activity of radioactive urea. 60 min. after the injection, the animal was killed by decapitation and the brain analysed for radioactive urea. As a control for possible injection of urea-^{14}C as a contaminant of the arginine preparation as well as a control for urea formation from arginine as a result of the procedures employed, a litter-mate rat was killed and to the isolated brain was added 0·4 mgm. of guanido-^{14}C labelled L-arginine-hydrochloric acid. The brain was treated as described here.

Following the withdrawal of the blood samples from the experimental animal, 5 ml. of 15 per cent trichloracetic acid (TCA) were added and the samples were homogenized. 8 mgm. of unlabelled carrier urea were then added to the homogenates; the samples were centrifuged and the supernatant solutions were decanted and saved. The TCA from these fractions was then extracted with carbon tetrachloride. The samples were then taken almost to dryness with a rotary evaporator and the insoluble dixanthydrol derivative of urea was prepared and recrystallized to constant specific activity. The brain was homogenized and urea was isolated from the acid-soluble fraction by ion-exchange column chromatography. A derivative was prepared as described here.

Table 1. Specific Activity of Blood* and Brain* Urea Samples

Sample	Time (min. after injection)	Specific activity of urea (counts/min./mgm. urea)
Blood 1	18	3 × 10^3
2	20	3 × 10^3
3	30	3 × 10^3
4	40	5 × 10^3
5	50	6 × 10^3
6	57	7 × 10^3
Brain	60	250 × 10^3

* The whole rat brain contains 0·5 mgm. urea, and 0·5 ml. rat blood contains 0·29 mgm. urea.

Analyses for radioactivity and urea content were performed in a manner reported previously[1].

The results presented in Table 1 show that the specific activity of the brain urea is at least thirty times as great as the highest blood urea specific activity. The maximum urea-^{14}C contamination as determined by the specific activity of urea in the control brain is 6 × 10^3 counts/min./mgm. urea. If the brain urea were derived only from exogenous sources and was transported to the brain via the blood, then the brain urea specific activity could not be higher than that of the blood[5]. The fact that it is many times greater than the blood level, at all intervals in which blood was collected, is proof of endogenous brain urea synthesis from arginine.

Note: Ratner *et al.* have shown recently in partially purified rat-brain proteins that arginase is present; this is verified by our *in vivo* work[6].

This investigation was supported by a research grant *M*-4356 (*A*) from the National Institute of Mental Health.

Antibody Response in Rabbits following Injection of Sheep Erythrocytes into Lateral Ventricle of Brain

Immunological studies of the cerebrospinal fluid have been confined mainly to the passage of antibodies from plasma into the cerebrospinal fluid[1]. However, the investigation of exchange between cerebrospinal fluid and blood has revealed that various electrolytes[2], dyes[3] and proteins[4] may find their way from cerebrospinal fluid into general circulation. Furthermore, some data[5] indicate that red blood cells cross cerebrospinal fluid-blood barrier. It seemed, therefore, advisable to approach the immunological sequences following the injection of heterologous erythrocytes into lateral ventricle of the brain.

Table 1. PEAK AGGLUTININ AND HÆMOLYSIN TITRE ($\log_2$) IN THE SERUM AND CEREBROSPINAL FLUID (CSF) OF RABBITS RECEIVING SHEEP ERYTHROCYTES INTO THE LATERAL VENTRICLE OF THE BRAIN

Rabbit No.	Agglutinin									Hæmolysin

* Day when the rabbits were killed.

Young adult rabbits weighing 2·8–3 kgm. were used. A permanent cannula described by Feldberg and Sherwood[6] was implanted aseptically under pentobarbitone anæsthesia into the left lateral ventricle of the brain. The cannula was inserted at right angles to the bone, 7–8 mm. deep. The point of insertion lay 2 mm. lateral from the sagittal suture and 2 mm. behind the coronal suture. After the cannula was screwed into the skull and communication with the ventricular fluid was established, it was fixed to the bone by 'Texton' (S. S. White Co. of Great Britain, Ltd., London). Four days later the rabbits were treated for three successive days with a 5 per cent suspension (spectrophotometrically standardized) of washed sheep red cells. Two injections of 0·3 ml. each were performed daily, separated by a 1-hr. interval. The injections were all made into the lateral ventricle of the brain. After the last injection of antigen rabbits were bled every second day. The sera were heated at 56° C. for 20 min. and stored at −20° C. until titrated. Twelve days after the last injection the cerebrospinal fluid was withdrawn from the cisterna magna. The cerebrospinal fluid obtained was perfectly clear and not contaminated with red cells. Rabbit sera and cerebrospinal fluids were investigated for the presence of hæmolysin and agglutinin. The hæmolysin titration was essentially the same as described by Kabat and Mayer[7]. Hæmolytic activity was measured in 50 per cent units in the presence of five 50 per cent units of complement. Veronal buffered saline containing optimal concentration of magnesium and calcium ions was used for all washings and dilutions. The agglutinin content of sera and cerebrospinal fluids was determined by a semi-quantitative agglutination technique. Samples of rabbit sera and cerebrospinal fluids taken prior to the administration of sheep red cells were also investigated for the presence of hæmolysin and agglutinin.

Table 1 summarizes the results. It was found that cerebrospinal fluid, prior to the injection of antigen, did not exhibit hæmolysin and agglutinin activity, although natural antibodies were present in the serum. However, when the concentration of hæmolysin in the blood was sufficiently high it was possible to detect small amounts of these antibodies in the cerebrospinal fluid[8]. The injection of sheep erythrocytes into the cavity of rabbit brain was accompanied by an increase in antibody formation, the production of hæmolysin being much higher than that of agglutinin. Despite a high concentration of hæmolysin in the serum, only traces of that antibody were found in the cerebrospinal fluid. In a preliminary work it was noticed that rabbits which received only one intraventricular injection of sheep red cells manufactured specific antibodies at a very low level.

Bowsher[4] demonstrated that radioactive homologous serum protein, when injected into the subarachnoid space or ventricular cavities of the cat brain, was absorbed by different routes (leptomeningovascular, perineuro-lymphatic and/or ependymal). In rabbits we have also observed (unpublished experiments) that human γ-globulin inoculated into lateral ventricle may find its way to the general circulation, and provoke the appearance of specific precipitin in the serum. With rabbit serum taken 6 days after antigen injection a well-defined precipitin line was revealed by diffusion gel technique. The clearance of red cells from the cerebrospinal fluid, however, seems to have a separate mechanism. Essick[5] states that mesothelial cells may act as macrophages. Dupont *et al.*[9], using tagged red cells, have recently shown that the transfer of erythrocytes from cerebrospinal fluid to plasma is carried out by the mesothelial-lining cells of the subarachnoid space. These cells phagocytize erythrocytes and migrate towards the blood, thus causing slow appearance of radioactivity in the circulation. It may be supposed, therefore, that this slow removal of red cells from the cerebrospinal fluid to blood may act as a prolonged stimulus on antibody-producing apparatus, resulting in a significant increase of antibody in the serum. Finally, it seems that the intraventricular route of antigen administration offers a useful tool in the hands of an immunologist, and provides a new approach to the immuno-physiological examination of the central nervous system.

Relationship between the Decrease in Urinary Excretion of Histamine and the Initiation of the Labour Process

As has been shown by Kahlson *et al.*, in rats fed on a histamine-free diet, the urinary excretion of histamine begins at about the fifteenth day of pregnancy and increases rapidly. The peak value occurs 1 or 2 days before birth, then falls steeply to the pre-pregnant level. The increase in histamine excretion depends on the number of young in the litter; the larger the number, the greater the increase in histamine excretion[1].

Investigations were made to demonstrate the relationship between the decrease in histamine excretion and the initiation of the labour process. Observations were made on white laboratory rats, fed on a normal diet. The method described in detail by McIntire, Roth and Shaw[2] was adapted to measure the amount of histamine in urine.

Table 1. Mean Daily Excretion of Histamine (μgm.)

		Control animals	Experimental	
Before pregnancy		50	50	
Days after mating	15	120	130	
	20	880	750	
	21	104	700	Administration of histamine
	22	60	750	
	23	—	200	
	24	—	60	
	25	—	100	

Two days before the time of the expected parturition, that is, just before the onset of the period of low histamine excretion, 1·5 mgm. of histamine hydrochloride daily, in three doses, was injected subcutaneously during light ether anæsthesia. In this way the pretermal decrement in urinary histamine was prevented, and the high daily excretion (500–850 μgm.) was maintained artificially for two days.

It has been observed that, after the last injection of histamine, urinary excretion fell gradually during 1·5–2 days to about the pre-pregnant level. The labour process began about 30 hr. after decrease of the histamine-level. In this way the pregnancy was prolonged for two days. Some of the young in the litter from such a prolonged pregnancy were born dead; others showed after-birth weak respiratory movements, and died soon afterwards.

RADIOBIOLOGY

Estimation of Time of Generation of Living Cells

The use of tritiated thymidine as a labelling agent has greatly facilitated examination of nuclear reproduction and cellular proliferation[1–4]. In such work, it has been customary to focus attention on the proliferation and fate of the cells that are labelled. Mendelsohn, however, has studied the fate of both labelled and unlabelled cells in tumours of mice and has used data obtained from both the labelled and unlabelled cell populations to derive the ratio of proliferative cells to total cells (the growth fraction)[5,6]. In the method presented here, applicable whenever a cohort of cells (that is, a fraction of the population) is labelled, the data for the labelled and unlabelled cells are analysed separately. In this way more information is obtained than when either only the labelled cells are studied or when data for the two cell populations are combined. The generation time of both labelled and unlabelled cells can be determined and compared, thus providing a method by which one aspect of toxicity of tritiated thymidine can be examined.

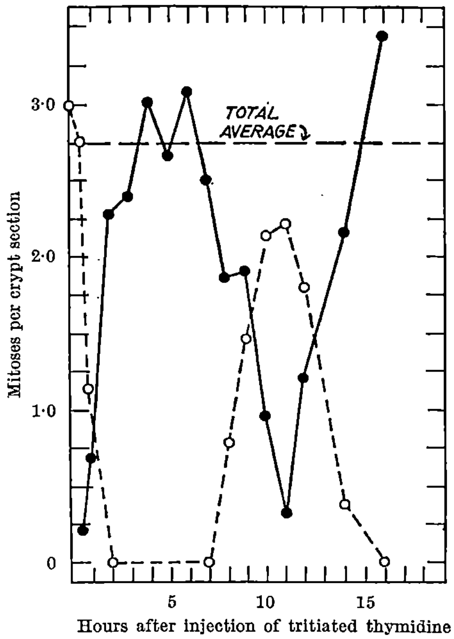

Fig. 1. Number of mitotic figures per crypt section as a function of time after injection of tritiated thymidine: dashed curve, unlabelled figures; solid line, labelled figures. 'Total average' represents the total number of mitotic figures per crypt section averaged over the 16-hr. observation period

The following experiment illustrates the use of this method in the determination of generation time and mitotic time of the labelled cells, and generation time of the unlabelled cells. CAF_1 mice, 93 days old, (weighing 25 gm.) received intraperitoneally 50 μc. of tritiated thymidine (360 mc./mM). Thereafter at intervals up to 16 hr., 1 or 2 animals were killed to obtain samples of the duodenum. Autoradiographs were made[7] of 3μ duodenal sections pre-stained by the Feulgen reaction. For each time of killing, the numbers of labelled and unlabelled mitotic figures (all stages) were counted in about 20 crypts of Lieberkühn (about 1,000 cells). The mean numbers of labelled (M_l) and unlabelled (M_u) mitotic figures per crypt section were calculated from these data and plotted as a function of time (Fig. 1).

Generation Time. In the case of the unlabelled cohort, the curve traced by M_u began at 3·0 mitoses per crypt section; at 2 hr. after injection the value was zero; the value began to increase again at 7 hr., and a peak value of 2·2 was reached at 11 hr. Thus a cycle was completed in 11 hr., which is an estimate of the generation time. If the duration had been measured between similar points (in the range $M_u = 1·5–0·5$) on the descending limbs of two successive cycles, it would have been about 12 hr. We therefore took the generation time to be 11·5 hr.

In the case of the labelled cohort, the curve traced by M_L began at zero and after passing through a peak of about 3 mitoses per crypt section (in agreement with the initial value for the unlabelled cohort) returned to a minimum value at 11 hr. The generation time was therefore estimated as 11 hr., in good agreement with that for the unlabelled cohort. The estimate based on the time elapsing between successive M_L values of 3 (approximately the maximum) was 11·3 hr. We therefore took the generation time to be 11·2 hr. This result is in good agreement with our previously reported figure of 11·5 hr.[8].

For 2–9 hr. inclusive, the values of M_L (1·85–3·07, Fig. 1) had standard errors of 0·25–0·54. The full statistical analysis of these and further data will be discussed in a later report.

Mitotic Time. The mitotic time T of the labelled cells can be estimated as follows: $T = G\bar{I} = G\bar{N}/P$ where for the labelled cohort, G is generation time, $\bar{I}$ is mean mitotic index, $\bar{N}$ is the average number of cells in mitosis (per crypt section) throughout the generation cycle, and P is the number of proliferative cells (per crypt section).

The generation time of the labelled cells (G_L) was 11·5 hr. The average number of labelled cells in mitosis ($\bar{N}_L$) was determined by taking the average of 11 consecutive hourly determinations of labelled cells in mitosis (M_L) (Fig. 1); $\bar{N}_L = 1{\cdot}91$. The number of labelled proliferative cells (P_L) was taken as the number of labelled cells (per crypt section) ½ hr. after the injection of tritiated thymidine, when the initial labelling was maximal and no labelled cells had gone through mitosis; $P_L = 15{\cdot}5$.

From these data it follows that T (for labelled cohort) $= 11{\cdot}2 \times 1{\cdot}91/15{\cdot}5 = 1{\cdot}38$ hr.

The same procedure can be used to obtain the mitotic time of the unlabelled cells when the number of unlabelled proliferative cells can be accurately assessed. As yet we have not established the number of unlabelled proliferative cells at the necessary time-intervals with sufficient accuracy to calculate the mitotic time of the unlabelled cells.

The agreement between the results for the labelled and unlabelled cells indicates that the dose of tritiated thymidine used (50 μc. per animal) did not affect the generation time. It should be noted that this result applies only to that part of the first generation-cycle that has been studied. It remains to be determined whether or not the duration of subsequent cycles is affected.

This work was performed under the auspices of the U.S. Atomic Energy Commission.

Leukæmia in the *AkR* Mouse after X-Irradiation *in utero*

It is known that the incidence of lymphoid leukæmia in mice is influenced by X-irradiation of the adult[1]. In strains where the spontaneous incidence of the disease is low, it is increased; but it may be decreased when the incidence is already high[2]. In the high-leukæmia strain *AkR* mouse, it has been shown that, after doses of X-rays of between 50 and 500 r. to the new-born animal, there is a reduction of the usually high incidence of leukæmia, slightly among females but more markedly among males even at the lowest doses[3].

The work reported here is part of an investigation of leukæmia after small doses of X-rays to the mouse fœtus. Retrospective and prospective studies of leukæmia after diagnostic X-rays to the fœtus in man have given conflicting results[4]. The present experiment was designed to determine whether there is an alteration of incidence of leukæmia or latent period in the high-leukæmic strain *AkR* mouse after small doses of X-rays to the fœtus.

AkR female mice were mated to *AkR* males which were their respective litter mates and then put into one of three treatment groups after the appearance of copulation plugs: (1) those to be sham irradiated; (2) those to receive 5 rads at the level of the gravid uterus on day 7½ and again on day 14½ of pregnancy; (3) those to receive 25 rads at the level of the gravid uterus on day 7½ and again on day 14½ of pregnancy.

The X-ray source was a 'Resomax' operating at 300 kV. and 13 m.amp. (filtration 0·1 mm. tin + 0·5 mm. copper + 1·0 mm. aluminium). The dose-rate was 5 rads per min., at a treatment distance of 140 cm. The females were allowed to rear their litters, which after weaning at 6 weeks were kept 6 per cage (2 from each treatment group) under identical conditions, males and females separately.

All animals were observed and eventually killed when moribund. Diagnosis of leukæmia was verified by autopsy, blood count and blood and bone marrow smears. Any doubtful cases were investigated by bioassay. The histological appearance of the leukæmia occurring in all groups conformed to that of the spontaneous lymphoid leukæmia characteristic of this strain.

A total of 353 animals was observed, 178 males and 175 females, progeny alive at the time of the first case of leukæmia at 180 days and deemed to be at risk. Table 1 contains a summary of results obtained after all the animals had died. No real difference in incidence of leukæmia can be shown in the female groups. In the males, however, the group treated with 50 rads shows a lower incidence of leukæmia than that of the control or of the 10-rad groups.

The mean time to death from leukæmia in the female groups seems to be unaffected by irradiation. In the males, however, the mean time in the 50-rad group is longer than in the 10-rad or control groups. (An analysis of variance shows this lengthening to be significant at the 10 per cent level.) The times to death from leukæmia for individuals in each group show a normal distribution against the logarithm of the time. The tail of the distribution curve suggests that all animals would have succumbed to leukæmia if death from other causes had not intervened. In order to arrive at a more realistic mean for time to death from leukæmia in each group, allowance should be made for animals dying from other causes. The individual times of death for such animals have been

Table 1

Total dose (rads)	No. of animals at risk		Per cent leukæmia		Corrected mean time to death from leukæmia (days)	
	Males	Females	Males	Females	Males	Females
0	68	62	86·8	96·7	340 (333)±11	288 (288)±10
10	56	58	85·9	89·6	341 (333)±12	292 (290)±10
50	54	55	72·2	90·9	378 (362)±15	297 (294)±10

adjusted on the basis of a preliminary estimate of the distribution. The correction involves an addition of small magnitude which gives the probable time of death from leukæmia if the other cause had not operated. Corrected means are shown in the right-hand column of Table 1 with uncorrected means in parentheses.

It would appear that, after the doses of X-rays used, there is no evidence of either increase in leukæmia incidence or of accelerated disease in either males or females irradiated *in utero*. On the contrary, in males after 50 rads there may be a decrease in incidence of leukæmia with an increased mean time to death from leukæmia.

HÆMATOLOGY

Hæmagglutinins from *Clerodendrum viscosum* Vent

THE capacity of certain plant proteins closely to simulate the action of various human blood group specific agglutinins is well known; the subject has been reviewed by me[1]. Almost all strong blood-group-specific plant agglutinins have been obtained from the genus Leguminosae; recently a good anti-A (anti-A_1) was found in the seeds of *Hyptis sauveolens* Poit of the genus Labiatiae[2]. Examination of other non-leguminous plants has now revealed specific agglutinins in the fruit pulp of *Clerodendrum viscosum* Vent (syn. : *C. petasites* Lour; *C. infortunatum* Cook *et al.*, non-Gaert and non-Linn), of the natural order Verbenaceae, a gregarious shrub commonly found throughout India, Burma, Ceylon and the Andaman Islands.

The fruit is about the size of a large garden pea. It has a relatively big seed which contains weak non-specific agglutinins. The fruit pulp was carefully separated from the seed, ground in three times its volume of physiological saline, and filtered. The filtrate, when tested for avidity by the tile method, and titrated by the conventional tube method, was found to agglutinate red cell suspensions of various ABO blood-groups and sub-groups in the following order: O (strongest), A_2, A_2B, B, A_1, A_1B; H-negative cells were not agglutinated. The reactions were not influenced by the Le^a or Le^b status of the erythrocytes. Thus the agglutinins of *C. viscosum* are anti-H or anti-O.

The agglutinin is inhibited, but not completely neutralized, by a 1/1,000 (w/v) aqueous solution of purified H-substance; it is not inhibited by identical concentrations of similarly purified A, B or Le^a substances. Similarly, it is inhibited, but not neutralized, by secretor salivas; it is not inhibited by non-secretor salivas. The agglutinin is inhibited (two tubes) by 2 per cent salicin; it is not inhibited by 2 per cent L-fucose. It thus belongs to the little-understood group of anti-H agglutinins, which are not inhibited by L-fucose, a sugar which is an important structural determinant of H-specificity[3].

The *Clerodendrum viscosum* agglutinin would be useful for making the A_1: A_2 distinction, particularly when used in parallel with the anti-A_1 agglutinin from *Dolichos biflorus* seeds. It is not recommended for general use in making the secretor : non-secretor distinction, for which the anti-H agglutinin from *Ulex europaeus* seeds would be more reliable. However, it could be used for this purpose by those familiar with its properties, particularly in countries such as India, in which other plant sources of anti-H are not readily available. It might also be useful, as an addition to the heterogeneous ranks of anti-H reagents, in research on the H-character or characters of erythrocytes and secretions.

I am indebted to Prof. W. T. J. Morgan, for the blood-group substances and sugars; to V. B. Kumar, for collecting the plants and for technical assistance; and to the Botanical Survey of India, Poona, for the identification.

Hæmoglobin *P* in a Family of Southern Italian Extraction

THE larger part of abnormal hæmoglobins described in world literature has been observed, in sporadic form, among the people of Italy. As a matter of fact, Silvestroni and Bianco *et al.* have identified[1–3] not only many cases of hæmoglobin S, the presence of which in Italy was known for some time, but also cases of hæmoglobins L, D, G, K, H and A_2 abundant in non-microcythæmic (or thalassæmic) subjects.

Now another abnormal hæmoglobin, P, has been found in four members of an Italian family originating from Calabria. During work on the electrophoresis of the hæmoglobin of microcythæmics, a carrier of microcythæmia (or thalassæmia minima), F. Bettina, aged seventeen, was first found, and later three of her brothers (F. Francesco, aged

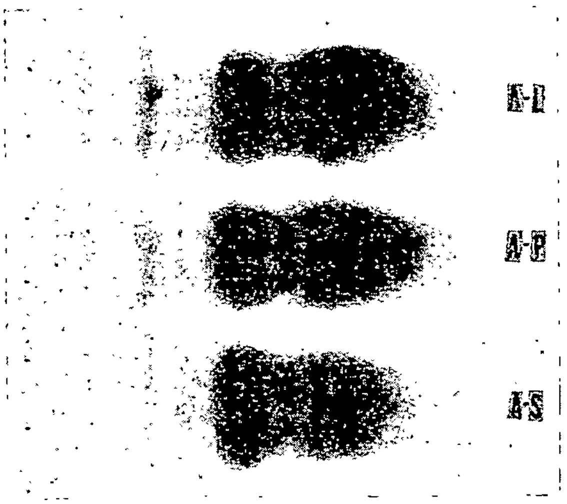

Fig. 1. Paper electrophoresis of hæmoglobins *A–L*, *A–P* and *A–S*, glycine buffer *p*H 8·8, ionic strength 0·04. Stained with bromophenol blue. Mobility of the hæmoglobin slow fraction identical in the three samples

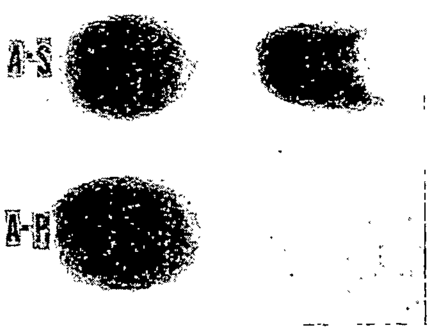

Fig. 2. Electrophoresis in agar gel of hæmoglobins *A–S* and *A–P*. Citrate buffer *p*H 6·2, ionic strength 0·05. Stained with bromophenol blue. Complete lack of separation of hæmoglobin *P* from hæmoglobin A_1

twenty-three ; F. Giuseppina, aged twenty-seven ; F. Maria, aged fifteen) and their grandfather on the mother's side (T. Francesco, aged seventy) were found carriers of a slow hæmoglobin ; all four were enjoying good health and their hæmatological pattern was perfectly normal, without presenting any character reflecting the simultaneous presence of microcythæmia, the fraction of hæmoglobin *a–r* being below 2 per cent and that of hæmoglobin A_2 between 2 and 2·60 per cent, whereas in the microcythæmic member it was 4·50 per cent. The slow hæmoglobin was present in all four subjects to the extent of about 50 per cent.

An investigation to determine the characters of this abnormal hæmoglobin has produced the following results :

(1) In paper electrophoresis at *p*H 8·6, the mobility of the slow hæmoglobinic fraction was equal to that of hæmoglobins *S*, *D* and *L* (Fig. 1).

(2) Even on starch-block and on starch-gel electrophoresis at *p*H 8·6 the slow hæmoglobin separated from hæmoglobin A_1 with the same mobility as that of hæmoglobin *S*.

(3) In paper electrophoresis and starch gel at *p*H 6·2–6·5 hæmoglobin A_1 and the slow hæmoglobin did not separate, and the hæmoglobin spot had the same aspect as that of hæmoglobin A_1 only.

(4) Even in agar gel at *p*H 6·2 the slow hæmoglobin did not separate from hæmoglobin A_1 (Fig. 2), contrary to hæmoglobins *S* and *L*, and like hæmoglobin *D*.

(5) In column chromatography using 'Amberlite *IRC*–50' at *p*H 6, the slow fraction did not separate from hæmoglobin A_1; the hæmoglobin band was, however, much wider than that of hæmoglobin A_1 alone, extending from this to the band of hæmoglobins A_2, *G* and *S* (Fig. 3).

(6) The ultra-violet spectrum of the slow hæmoglobin, isolated after starch block electrophoresis, was quite normal and identical with that of hæmoglobin A_1 of the same subject.

(7) In alkaline denaturation test, the isolated slow hæmoglobin behaved as hæmoglobin A_1 and denatured completely within 60 min.

These characters of the slow hæmoglobin examined correspond clearly with those described for hæmoglobin *P*[4–6]; in particular, the more specific characters of this hæmoglobin and which more clearly distinguish it from the other slow hæmoglobins (failure to separate from hæmoglobin A_1 in agar gel and during chromatography at acid *p*H) are certainly present in the hæmoglobin under examination.

The only discordant point appears to be that of electrophoretic mobility at alkaline *p*H, which in the initial observation of Schneider and Haggard[4,5] was defined as equal to that of hæmoglobin *L*, even though it has been observed in analyses between glass plates or electrophoresis of less than 18 hr. duration, that "its pattern was indistinguishable from that of hæmoglobin *A–S*". In previous analyses of other slow hæmoglobins, Silvestroni and Bianco *et al.*[3] have been able to demonstrate that the mobility of a slow hæmoglobin fraction is, within certain limits, dependent on its concentration in the hæmoglobin mixture, that is, the lower the aforesaid concentration, the more it decreases. This fact has been fully confirmed also for the present slow hæmoglobin, and comparisons of electrophoretic mobility have therefore always been made with mixtures of hæmoglobins containing the same percentage of slow hæmoglobin.

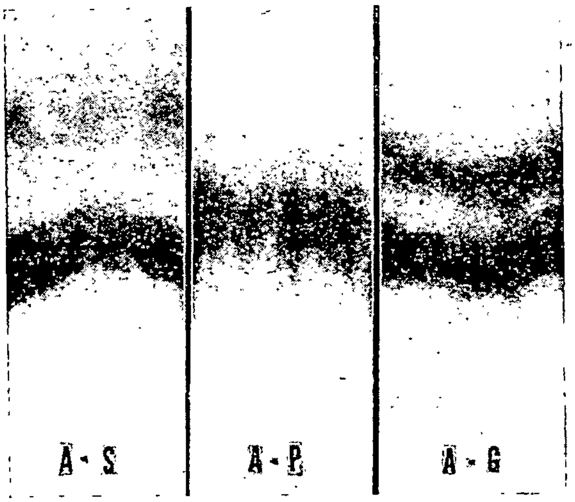

Fig. 3. Chromatography on columns of 'Amberlite *IRC*-50' of hæmoglobin *A–S*, *A–P* and *A–G*. Lack of separation of hæmoglobin *P* from A_1 and formation of a diffused hæmoglobin band

Therefore, as the difference of mobility is very slight and also so easily affected by the 'concentration factor', it can be stated, in conclusion, that it cannot have any value.

Hence the hæmoglobin described here is certainly a new case of hæmoglobin *P*: it seems that this is the fourth observation described in the literature after that of Schneider and Haggard[4,5], Dherte *et al.*[6] and Lambotte-Legrand *et al.*[7]; the second in which hæmoglobin *P* is present without any association of other slow hæmoglobins (*S*); and it is the first case of hæmoglobin *P* found in Italy.

PATHOLOGY

Sensitivity of Mice to Bacterial Lipopolysaccharide following Alteration of Activity of the Reticulo-endothelial System

It has generally been assumed that resistance of animals to the pyrogenic and lethal effects of bacterial endotoxin is largely dependent on the phagocytic capacity of the reticulo-endothelial system. Thus it has been shown that stimulation of the reticulo-endothelial system with non-lethal doses of bacterial lipopolysaccharide or endotoxin results in protection of the animals against a subsequent lethal dose of endotoxin[1]. Again, numerous workers have demonstrated that a 'blockade' of the reticulo-endothelial system by colloidal particles, for example saccharated iron oxide, thorotrast and trypan blue, increases the sensitivity of the animals to the lethal effects of these substances[2]. Recently, however, it has been shown that in certain circumstances it is possible for mice to possess an increased phagocytic activity, as measured by their ability to clear colloidal carbon, and yet be highly sensitive to the effects of endotoxin. This can be seen during the course of an intracellular infection[3], or following the administration of zymosan[4]. The apparent contradiction of these results has yet to be resolved, and it is not unlikely that such resolution may lead to an elucidation of the mode of action of the endotoxins.

Recently, Stuart *et al.*[5,6] have shown that certain fatty acid esters can produce marked stimulation or depression of the phagocytic activity of the reticulo-endothelial system, as measured by the granulopectic test[7]. Results of histological studies (to be reported elsewhere) have shown that glycerol trioleate (triolein) produces a marked increase in the activity of phagocytic cells of the liver and spleen, whereas ethyl stearate causes a striking reduction in their number; these effects are reflected in a respective increase or decrease of phagocytic indices (*K*) of mice treated with these substances. The use of these agents might help to clarify the role of the fixed phagocytic cells in protection against endotoxin.

Male mice from a single source, weighing 15–20 gm., were used throughout these experiments. Susceptibility of animals to a single endotoxin (Difco *Escherichia coli* 'O'111: *B*4 lipopolysaccharide) following treatment with the lipids was compared by two experimental systems. In one, the LD_{50} of the endotoxin in the variously treated animals was determined, whereas in the other the survival of groups of mice receiving an injection of slightly more than 1 LD_{50} of the endotoxin (for normal animals) was estimated. Groups of animals, previously treated with a non-lethal dose of *E. coli* lipopolysaccharide, were always included for comparison. Colloidal suspensions containing 20 per cent (v/v) triolein and 20 per cent (w/v) ethyl stearate were prepared as described previously[5]; the lipopolysaccharide was dissolved in isotonic saline in a concentration of 200 μgm./ml. The following dosage schedule was used throughout the experiments: triolein, 0·05 ml./20 gm. mouse (11·5 mgm.), ethyl stearate, 0·1 ml./20 gm. mouse (20 mgm.) and lipopolysaccharide 0·1 ml./20 gm. mouse (20 μgm.). All injections were given intravenously. 24 hr. later the mice, including appropriate groups of normal animals of the same age, were challenged by intraperitoneal injection of a saline solution of *E. coli* lipopolysaccharide. The dose used depended on the form of the experiment and is recorded in Tables 1–3. The mice were observed over a period of 48 hr.; LD_{50} values were calculated and compared by the method of Litchfield and Wilcoxon[6]. Tables 1 and 2 record the results of these experiments.

Table 1. LD_{50} of *E. coli* Lipopolysaccharide in Mice treated with Lipopolysaccharide and Simple Lipids

Treatment	Survival-rates following endotoxin doses of (in μgm.)					LD_{50} (μgm.) with 19/20 confidence limits
	500	400	300	250	100	
Normal	1/10	2/10	6/10	8/10	10/10	325 (276–357)
Lipopolysaccharide	5/8	8/10	7/9	9/10	9/9	630 (437–908)
Triolein	1/10	1/10	1/10	4/10	7/10	175 (132–234)
Ethyl stearate	3/10	6/9	8/10	8/10	9/10	445 (326–615)

Survival-rate = No. alive/No. tested.

Table 2. Survival of Animals treated with Lipid or Lipopolysaccharide following Challenge with 400 μgm. *E. coli* Lipopolysaccharide

Treatment	Survivors/tested	Survival (per cent)
Normal	19/40	47·5
Lipopolysaccharide	37/40	92·5
Triolein	6/40	15
Ethyl stearate	21/40	52·5

Table 3. Phagocytic Indices of Mice 24 hr. after Treatment with Lipids and *E. coli* Lipopolysaccharide

Treatment	Animals	Mean *K** values	Mean *α** values
Normal	10	0·037	5·4
Lipopolysaccharide	10	0·096	7·0
Triolein	10	0·105	7·7
Ethyl stearate	10	0·0125	3·4

* *K* and *α* values were determined at a dosage of 8 mgm./100 gm.

The granulopectic activity of mice 24 hr. after injection of the lipids or the *E. coli* lipopolysaccharide was determined by the technique of Halpern *et al.*[7]. The phagocytic index (*K*) and the corrected phagocytic index (α) were determined at a dosage-level of carbon of 8 mgm./100 gm. Results of these investigations are summarized in Table 3.

Although triolein stimulates as good, or better, phagocytic activity as does lipopolysaccharide treatment, these results demonstrate that this lipid renders the mice significantly more susceptible to endotoxic activity. Again, contrary to the findings with 'blockaded' animals, the removal of phagocytes following treatment with ethyl stearate does not appreciably enhance susceptibility to endotoxin. It is arguable that the endotoxin may be taken up by phagocytic cells other than those of the liver and spleen, although it should be noted that in normal animals these organs together remove more than 80 per cent of the endotoxin[9].

The increased susceptibility of animals following triolein is not so great as that recorded following *BCG* infection or zymosan treatment. This difference may be related to the finding that, after either *BCG* infection or administration of zymosan, a marked granulomatous response occurs, whereas the simple lipid apparently exerts its action only on those sessile phagocytic cells which are in contact with the blood. At this stage the results suggest that endotoxin activity is dependent on the rapidity of uptake by certain cells, particularly those of the reticulo-endothelial system. Certainly it seems that the more phagocytes present in the liver and spleen the more sensitive are animals to endotoxin; on the other hand, decrease in cell numbers appears to have, if anything, a slightly beneficial effect on the resistance of the animals.

Lipopolysaccharide treatment may involve not only an increase in phagocytic cells but also perhaps stimulation of intracellular mechanisms of detoxification. Nevertheless, the influence of endotoxin-neutralizing factors in sera cannot be overlooked in assessing the protective activity of these substances[10].

Non-Specific Immunity in Pneumococcal Infection of Mice

The development of early, non-specific protection against experimental infections with Gram-negative micro-organisms has been observed following injection of bacterial endotoxin, lipopolysaccharide and lipid *A*[1]. Reports of similar activities of these substances against infections with Gram-positive organisms are less numerous and have been substantiated only in the case of infection with *Staphylococcus pyogenes* or *Mycobacterium fortuitum*[2]. In an attempt to assess the role of phagocytosis by cells of the liver and spleen in this non-specific protection, we have utilized certain fatty acid esters which are capable of profoundly increasing or reducing the activity of these cells[3]. One of the experimental models selected for this work has been infection with *Streptococcus pneumoniae* in mice. Infections with this organism have usually been carried out by the intraperitoneal route and are highly lethal, unless the infection is modified by the classical means of active or passive immunization. In an attempt to demonstrate other, perhaps less potent, protective mechanisms, we felt that a less-virulent type of infection might be more appropriate. This has been achieved by using a strain of *Strep. pneumoniae* type 8, preparing the challenge inoculum in 0·1 *M* phosphate buffer at *p*H 7·4 and injecting the chosen dose of organisms by the intravenous route. Details of this technique will be published fully elsewhere.

Male mice derived from a single source and weighing 15–20 gm. were used. The effects of glycerol trioleate (triolein) and ethyl stearate treatment on the infection were compared with those of non-lethal doses of *E. coli* 'O'111 : *B*4 lipopolysaccharide (Difco). The method of preparing the lipid suspensions has been described previously[3]. The following doses of the substances were given to individual groups of mice by the intravenous route: triolein, 0·05 ml. of 20 per cent (v/v) suspension (11·5 mgm.), ethyl stearate, 0·1 ml. of 20 per cent (w/v) suspension (20 mgm.) and *E. coli* lipopolysaccharide, 0·1 ml. of 200 μgm./ml. solution (20 μgm.). 24 hr. later all the mice, including appropriate groups of normal animals, were injected intravenously with *Strep. pneumoniae* derived from an over-night culture in horse digest broth, and diluted appropriately in phosphate buffer. The number of organisms in the challenge dose was determined by viable count using the Miles and Misra technique[4]. Injections of the lipids and lipopolysaccharides were repeated 24 hr. later. The mice were observed for seven days and time to death within the groups was recorded. In Tables 1 and 2 are summarized the results of two experiments, one in which a constant challenge dose (about 4×10^4 organisms) was used, the other in which three challenge doses differing by ten-fold dilutions were given to various groups of animals.

It has been shown (preceding communication) that mice treated with lipopolysaccharide and triolein have a significantly higher phagocytic activity than normal when measured by the granulopectic technique[5]. Conversely, a marked suppression of phagocytic activity occurs following administration of ethyl stearate. These findings may be attributed to a marked increase or diminution of the hepatic and splenic phagocytes (Stuart, A. E., unpublished work). The results described here suggest that phagocytic reduction does not significantly affect the survival or time to death of the mice. However, a striking degree of

Table 1. Survival of Mice treated with Lipids and Lipopolysaccharide following Challenge with *Strep. pneumoniae* (4×10^4 Organisms)

Treatment	No. survivors / No. tested	Survivors (per cent)	Mean time to death (hr.)
Normal	2/20	10	56
Triolein	6/20	30	73
Ethyl stearate	1/18	6	66
Lipopolysaccharide	18/20	90	108

Table 2. Survival of Mice treated with Lipids and Lipopolysaccharide receiving Graded Doses of *Strep. pneumoniae*

Treatment	Survivors/tested receiving challenge doses of:		
	$2\cdot5 \times 10^5$ organisms	$2\cdot5 \times 10^4$ organisms	$2\cdot5 \times 10^3$ organisms
Normal	0/10	1/10	9/10
Triolein	3/10	4/10	9/10
Ethyl stearate	0/10	1/10	6/10
Lipopolysaccharide	7/10	10/10	10/10

protection against infection can be achieved with lipopolysaccharide, and to a much less extent with triolein. There seems no doubt of the non-specific nature of this enhanced protection, which develops within 24 hr. This protection cannot be related to the properdin system, which has been shown to be effective only against Gram-negative organisms (ref. 1, *b*).

The difference in protection achieved with lipopolysaccharide and triolein is of particular interest. There is no observable difference in the ability of animals to clear colloidal carbon from the blood following treatment with either of these substances. It is generally assumed that the granulopectic test is a measure of an animal's ability to clear microorganisms from the blood as well[6]. This is substantiated by an experiment, the results of which are recorded in Table 3, in which the removal of viable pneumococci from the blood of animals was examined. Groups of mice treated with lipopolysaccharide or triolein were injected intravenously with approximately 1×10^6 organisms (derived from an overnight culture, as above) suspended in phosphate buffer. Immediately after injection and at 6-min. intervals thereafter up to 18 min., blood samples were removed from the retro-orbital venous plexus; ten-fold dilutions of the sample were prepared in phosphate buffer and viable counts were determined by the Miles and Misra method[4]. Logarithms of the counts plotted against time yielded approximately linear curves, and it was thus possible to express the rate of removal of organisms (K) in terms of the slope of the line.

The results suggest that the differences in effects observed with the lipopolysaccharide and glycerol trioleate cannot be explained in terms of rate of removal of the organisms from the blood. Rather it seems that the lipopolysaccharide treatment stimulates some factor which causes more rapid death of the organisms following their removal. This may be either a serum factor (non-specific opsonin) or an enhanced intracellular activity of the phagocytes stimulated by the lipopolysaccharide. Preliminary experiments suggest that opsonization *per se* may have no immediate influence in non-specific protection against the pneumococcal infection.

Table 3. Rate of Removal of Viable Pneumococci (K) in Mice treated with Lipid or Lipopolysaccharide

Treatment	Mean values of K	KT/KN
Normal	0·013	
Triolein	0·031	2·48
Lipopolysaccharide	0·035	2·68

KT/KN = Ratio of K values of treated to normal animals.

Increase in Specific Bactericidal Antibodies after Administration of Endotoxin

Many non-specific immune phenomena have been described in which animals became resistant to experimental infection following administration of antigenically unrelated materials. None has attracted more interest than the temporary state of enhanced resistance to infection with Gram-negative bacteria which develops in mice within hours after administration of antigenically unrelated bacterial endotoxins[1]. Among the many effects of endotoxins on the host is increased activity of the reticulo-endothelial system as shown by carbon clearance[2] and by removal of phosphorus-32 labelled endotoxin[3] or bacteria[4]. In addition, changes in the serum of endotoxin-treated animals have been reported, notably increased levels of properdin[5], bactericidins[6] and opsonins[7,8]. Passive transfer of opsonic capacity has also been demonstrated[4]. It is evident that these alterations in the host, individually or collectively, may contribute significantly to survival. Special emphasis has been placed on the non-specific nature of the humoral factors involved, because there has been abundant confirmation of activity against bacterial strains antigenically unrelated to the endotoxin used for stimulation. Cross-reacting antibodies[9] or a common antigen associated with the lipid complex of endotoxins[10] have therefore been suggested to account for these observations.

The serum bactericidal reaction against Gram-negative bacteria has been shown to depend on specific antibody, complement and divalent cations. We have developed a method for the determination of antibody based on this reaction[11]. Serum accessory factors, such as complement, are supplied in excess. The level of specific antibody in the serum under test is measured by the extent to which it restores bactericidal activity to absorbed human serum. In normal serum this method detects antibody against Gram-negative bacteria in amounts considerably less than

Table 1. BACTERICIDAL ACTIVITY OF MOUSE SERUM FOR *Salm. typhi* 0901

* Supplemented with absorbed human serum as a source of complement.

those required for agglutination of bacteria or antigen-coated red cells, namely, 0·001 μgm. antibody nitrogen in the case of antiserum to *Salmonella typhi*. The quantity of serum which gives 50 per cent bacterial killing is determined, with satisfactory reproducibility, by plotting log serum dose against probits of bacterial survivors. Our work has dealt predominantly with the mouse, because non-specific resistance has been investigated almost exclusively in this species. Mouse serum is not bactericidal, because its complement is not functional in this system; supplementation with heterologous complement is therefore essential for the assay. In our tests pooled normal human serum, from which antibody had been absorbed by heat-killed bacteria, served as the source of serum accessory factors.

With this method we have found that after administration of endotoxin to mice, in amounts which elicit so-called non-specific immunity, there is an increase in serum bactericidal activity against several antigenically unrelated strains of Gram-negative bacteria. For example, within 3 hr. after administration of 50 μgm./mouse of a *Shigella shigae* endotoxin, increased bactericidal activity for other bacterial strains was discernible which persisted for more than 48 hr.; by 96 hr. the level returned to normal. Table 1 shows the level of this increased bactericidal activity at 24 hr. Absorption of the serum with one Gram-negative serotype removed bactericidal activity for that strain, whereas the increased serum bactericidal activity against strains of other genera was retained. An illustrative experiment is summarized in Table 2. Thus the factors in serum responsible for the elevation of bactericidal effect not only have the functional characteristics of antibodies, but also are individually absorbable as would be expected of specific antibodies.

Additional evidence for the antibody-like character of the bactericidin was also obtained. Serum from endotoxin-treated animals, after absorption with heat-killed *Salm. typhi* 0901, still possessed increased bactericidal activity for *Escherichia coli* 0127. This absorbed serum, added as a supplement to normal mouse serum in a bactericidal test against *Salm. typhi* 0901, did not increase the bactericidal activity of normal mouse serum. Thus the increased bactericidal activity is due to specific antibody rather than to some non-specific factors.

The rise in bactericidal titre after administration of endotoxin is assumed to be due to a transitory effect of endotoxin on antibody-forming cells. This may involve either release of preformed antibodies or a temporary increase in the capacity of these cells to produce antibody. These results point to a temporary elevation of a whole array of specific antibodies rather than the appearance of non-specific or cross-reacting bacterial antibodies. Experiments are in progress to determine whether the reported increase in opsonic factors in mice, following the administration of endotoxin, involves the same specificities.

BIOLOGY

A Natural Population of Anomalous Branched Tapeworms, *Hymenolepis nana* (Cestoda: Hymenolepididae), in a Colony of *DBA/1* Mice

DURING work on metabolism of the dwarf tapeworm of mice (*Hymenolepis nana*), a natural infection with this parasite was found in a local colony of *DBA/1* mice (Curd's Caviary, Downey, California). Of 500 mice from this colony examined over a two-year period, 320 were infected with an average of 35 worms per mouse, varying from a single 12-in. worm to one or two thousand extremely small ones (demonstrating a 'crowding effect'). Among more than 12,000 worms recovered, approximately 5 per cent showed one of the following malformations or growth disturbances: (1) Partial twinning (Fig. 1*A*): forked posterior strobila; (2) lateral branching (Fig. 1*B*): new tissue outgrowth with varying degrees of differentiation; (3) dedifferentiation (Fig. 1*D*): groups of segments appearing as undifferentiated, vacuolated granular regions; (4) segment reversal: reversal of normal antero-posterior sequence of proglottides (Fig. 1*B*); (5) combination: dedifferentiation plus branch outgrowth (Fig. 1*C*); branch formation with segment reversal (Fig. 1*B*); multiple branching (Fig. 1*E*).

Cestode abnormalities reviewed by Foster, Faust, Clapham, Kuntz and Dollfus and others[1-7] include fenestration of groups of segments, fusion of strobilar loops, doubling and inversion of organs and other developmental irregularities, bud formation and dichotomy, spiral strobilization and polyradiate forms with additional suckers and marginal ridges. No one, however, has recorded recovery of numerous abnormalities from a single host population over a sustained period. The following circumstances are of added interest: (1) all aberrant worms were from a single commercial stock of mice, derived from the *DBA*/1 strain; (2) these hosts were maintained with a colony of Swiss Webster mice, with both groups showing a similar rate of infection, approximately 70 per cent, by *H. nana*. No branching was found among thousands of *H. nana* examined during a five-year period taken from 700 Swiss white mice from this colony. Nor were abnormal worms recovered from naturally infected mice from several commercial sources or from original Jackson Memorial Laboratory *DBA*/1 mice. Among infected Curd strain *DBA*/1 mice, approximately 60 per cent harboured abnormal worms, representing 800 or 5 per cent of the total recovered.

The commonest abnormality was a small nub or outgrowth of tissue showing considerable variation in length, orientation and degree of maturation. Less common were granulation and vacuolization, an apparent dedifferentiation or tissue destruction, bifurcation of posterior segments, and segment reversal. Multiple branching with varying degrees of maturation emphasize a capacity to bud or branch existing throughout the worm. Gravid branches were chiefly confined to twinned posterior ends. Abnormal worms were generally small, 3 cm. or less in length.

These malformations appear to be an interference with the normal pattern of differentiation and growth. New tissue development, usually confined to the neck area in tapeworms, appeared anywhere along the strobila, often accompanied by breakdown of organized regions. Subsequent differentiation and growth were delayed and abnormal. Branches usually showed more fully developed segments at branch-strobila junctions, the growing tip (equivalent to the neck of a normal worm) being carried out with the branch. No normal scolex was found, though neck-like, rounded branch ends often occurred (Fig. 1*B*, *C*). Twinned posterior ends formed by division of the terminal proglottides. This was followed by growth and maturation of the separate chains, their posterior portions therefore being most developed except for a terminal nub on the branch. Lateral branches probably formed similarly, but with sharply differing growth-rates for the two portions of the strobila.

These findings are of interest in terms of cestode growth patterns, antero-posterior differentiation and general growth control factors. Laboratory establishment of such an abnormal strain was therefore attempted. In three experiments, eggs cut from abnormal, gravid branches were fed in 0·1 ml. tap-water by pipette to six young non-infected *DBA*/1 mice. Gravid worms recovered were fed to normal white and *DBA*/1 mice and similarly passed through six generations of each host strain. No branched worms were recovered from any of these infections. In repeated feedings with intact abnormal worms to mice of Swiss, *DBA*/1 (Jackson Laboratory), and Heston/*A* (University of California Cancer Laboratory) strains, again only normal worms developed. Laboratory infection of Curd *DBA*/1 stock could not be attempted owing to absence of parasite-free animals from this source.

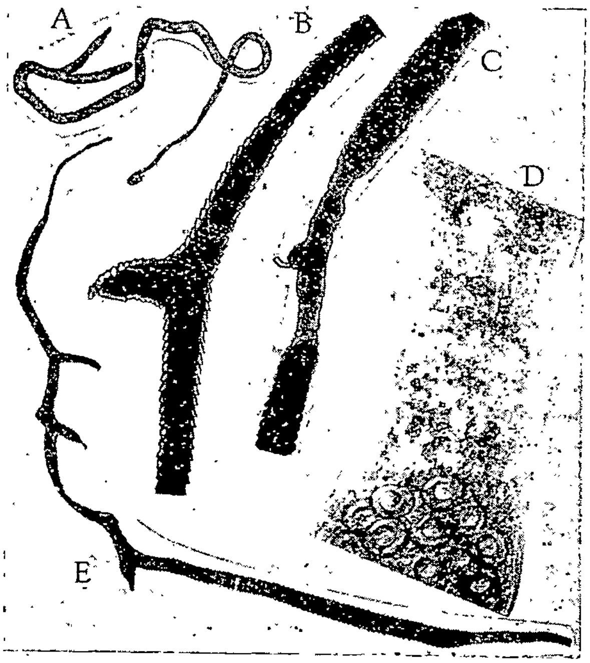

Fig. 1. Various expressions of tapeworm abnormality recovered from local strain of *DBA*/1 mice. *A*, Terminal twinning of strobila (× 5). *B*, Lateral branching showing terminal nub and reversed orientation of segments (× 10). *C*, Lateral branching with area of dedifferentiation (× 10). *D*, Detail of zone of granulation or dedifferentiation (× 110). *E*, Multiple branching, with division of segments of the most posterior branch (× 5)

Three groups of five grain beetles (*Tribolium confusum*), previously starved for seven days, were fed on abnormal gravid branches. No cysticercoids developed, owing either to reduced viability or insufficient numbers of eggs. However, normal cysticercoids developed when whole branched worms were exposed on filter paper to previously starved beetles. These cysticercoids produced only normal worms when fed to *DBA*/1 (Jackson strain), Heston/*A*, or Swiss Webster mice. Infections using grain beetle intermediate hosts were continued over four generations with the same result.

This phenomenon may represent a mutation activated by a specific host strain or an extraordinarily specific direct host-influence on an otherwise normal parasite. In either case, the high degree of dependence on the host for the expression of this abnormality emphasizes a remarkable specificity and an extreme degree of response of a parasite to its host.

surface activity

For all practical purposes surface activity began with Adam—or so, for convenience, the detergent chemist thinks. He does not mean the biblical Adam, of course, although there is an implied analogy which, conceding important happenings prior to Adam's appearance on the scene, nevertheless considers him to have directed matters on to a systematic course, and to have made it clear that not only could knowledge of the subject lead to understanding, but understanding to greater knowledge. Surface activity, in a sense, is not a property of surfaces but an effect induced therein by unbalanced molecular forces, and our knowledge and understanding of surface phenomena are derived from the pioneer work of Willard Gibbs, Langmuir, Rideal, McBain, Hartley Harkins and of Adam himself. Not that the subject is yet exhausted. The four volumes of the Proceedings of the Second International Congress on Surface Activity, to which Unilever scientists contributed, bear witness to the scope and diversity of its present applications—to flotation, adhesion, emulsion, lubrication and detergency—and to further problems that still await solution. Not unnaturally, Unilever has an almost generic interest in surface activity, as their products—soaps, fatty acids and fatty alcohols—have been classic materials for study. We move with the times, and Durham, Jones, McDonnell and their co-workers are investigating an ever-widening variety of surface active agents to elucidate their patterns of behaviour.

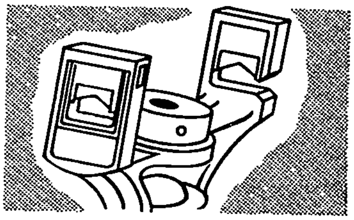
These world-famous balances, made by the OHAUS Scale Corpn. of New Jersey, U.S.A., are justly renowned for their outstanding value. They incorporate special, built-in high-quality features, listed below, making them more durable, more accurate and easier to operate. 1. Self-aligning, semi-rigid agate bearings. 2. Dust-proof, self-locking bearing covers. 3. Patented scale-plates with threaded hubs. 4. Elliptical check rods and spindles. 5. Relief-etched stainless steel beams. 6. Hollow-ground steel knife-edges.



Self-aligning, semi-rigid agate bearings give greater sensitivity, better reproducibility, and longer life.

Calories/gm. in Species of Animals

ANIMALS of seventeen species, representing six phyla, were burned in a miniature bomb calorimeter[1]. The data are presented as calories/ash-free gm. in Table 1 and as a histogram, Fig. 1.

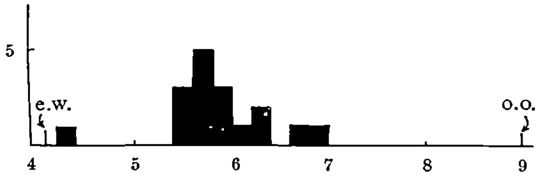

Fig. 1. Frequency distribution of the data in Table 1. The caloric values of egg white (e.w.) and olive oil (o.o.) have also been indicated.

Given a haphazard collection of species, any one of three mutually exclusive frequency distribution patterns might have been expected. These are listed below with the rationale of each :

(1) A normal, symmetrical distribution. This might be anticipated from the known biochemical similarities between animals. The variance would be related to slight biochemical differences and to errors of measurement.

(2) A skewed distribution with the modal frequency at or near the lower range limit. This might be anticipated, since there has always been selection for maximum number of reproducing progeny, but only sporadic selection for high-energy content/gm.

(3) Fairly great differences between major taxonomic groups with essentially normal distributions within each group. Many other properties of animals are common to a taxonomic category and differ between categories. Cal./gm. might be one such property.

The biological implications of the three possible distributions differ. The first distribution would imply that there is an optimal value of cal./gm., any deviation in either direction being selected against.

The second distribution would imply that there is some unique combination of components, characterized by a particular range of cal./gm., which just permits animals to maintain themselves. These components are essentially the same for all animals, and any combination with a lower cal./gm. value is non-viable. Higher values would be expected in animals that have temporarily accumulated fat, either because of unusually high food availability or as preparation for some period of fasting or stress.

Table 1. CAL./ASH-FREE GM. OF SEVENTEEN SPECIES OF ANIMAL

Common name	Species	Mean cal./ ash-free gm.	± 95 per cent confidence limit of the mean (corrected for small sample size)
Ciliate	*Tetrahymena pyriformis*	5,938	± 207
Hydra	*Hydra littoralis*	6,034	± 146
Green hydra	*Chlorohydra viridissima*	5,729	± 247
Flatworm	*Dugesia tigrina*	6,286	± 338
Terrestrial flatworm	*Bipalium kewense*	5,684	± 124
Acquatic snail	*Succinea ovalis* (without shell)	5,415	± 6
Brachiopod	*Glottidia pyramidata*	4,397	± 2,140
Brine shrimp	*Artemia* sp. (nauplii)	6,737	± 863
Cladocera	*Leptodora kindtii*	5,605	± 584
Copepod	*Trigriopus californicus*	5,515	± 277
Copepod	*Calanus helgolandicus*	5,400	± 197
Caddis fly	*Pycnopsyche lepido*	5,687	± 530
Caddis fly	*Pycnopsyche guttifer*	5,706	one determination
Spit bug	*Philenus leucophthalmus*	6,962	± 510
Mite	*Tyroglyphus lintneri*	5,808	± 446
Beetle	*Tenebrio molitor*	6,314	± 516
Guppie	*Lebistes reticulatus*	5,823	one determination

The third distribution would imply that cal./gm. is a secondary property in the evolution of animals and that the cal./gm. in any animal is a by-product of other selective requirements. This would be expected if, and only if, energy has generally not been limiting during the course of evolution.

So far as we have gone, the results suggest the second alternative distribution listed. Twelve of the seventeen determinations give results of 5,400–6,100 cal./gm. The one low value is from a moribund brachiopod (*Glottidia*). Two of the four high values were from animals that were about to go through a fast, the *Artemia* nauplii, since they were unable as yet to feed, and the *Tenebrio* larva, since it was about to pupate. The other two were from very well-fed situations, the *Dugesia* being from a laboratory stock culture fed on *Artemia* nauplii and the *Philenus* being taken from the field in late summer. The *Philenus* specimens included egg-laden females, but, unfortunately, they were not sexed on collecting. It seems likely that many herbivorous insects normally have superabundant food available[2].

Cal./gm. may provide an index of nutritional condition of animals in the field which would be considerably cheaper and as reliable as the elaborate sampling programmes now required.

This work has been supported by the National Science Foundation (*G*–9058). The calorimetric equipment was made available for testing on biological material by the U.S. Navy. We acknowledge the kindness of Dr. W. S. McEwan.

Manganese and Magnesium in the Grey Speck Syndrome of Oats

IT is generally recognized that the grey speck syndrome in oats is caused basically by manganese deficiency[1]. Opinions differ, however, on whether grey speck symptoms are due directly to manganese deficiency[1–3], or whether manganese deficiency functions indirectly by rendering the roots of the plant more susceptible to infection by rhizosphere organisms the toxic products of which give rise to the visual symptoms[4].

In consequence, the possibility of selecting breeding material resistant to grey speck is complicated, despite the variation in resistance reported by several investigators[5–7]. The present work is concerned with the investigation of possible differences in the critical levels of manganese in tissues of varieties of oats susceptible and resistant respectively to grey speck. For this purpose, the hexaploid oat variety Star (susceptible) and the diploid variety *S.*171 (resistant)[8] were used and grown in sand culture with a modified Shive solution and six levels of manganese, 0·0, 0·1, 0·2, 0·5, 2·0 and 5·0 p.p.m. Washed sand, de-ionized water and 'Analar' chemicals were used, but no elaborate precautions were taken to eliminate all manganese from the zero treatments.

Table 1. MANGANESE AND MAGNESIUM CONTENT OF OATS, SUSCEPTIBLE AND RESISTANT TO GREY SPECK DISEASE

Manganese treatment	Variety	Percentage Manganese Roots	Percentage Manganese Leaves	Percentage Magnesium Roots	Percentage Magnesium Leaves
0·0 p.p.m.	Star	0·00050	0·00050	0·45	0·55
	S.171	0·00256	trace	0·29	0·35
0·1 ,,	Star	0·00098	0·00175	0·44	0·50
	S.171	0·00300	0·00044	0·30	0·57
0·2 ,,	Star	0·00240	0·00200	0·46	0·45
	S.171	0·00350	0·00048	0·06	0·26
0·5 ,,	Star	0·00250	0·00800	*	0·27
	S.171	0·00500	0·00440	0·054	0·22
2·0 ,,	Star	0·00253	0·02000	0·25	0·35
	S.171	0·01250	0·01920	0·048	0·22
5·0 ,,	Star	0·00150	0·03900	0·23	0·48
	S.171	0·01350	0·02800	0·068	0·42

* No data.

The results (Table 1) show that for mature plants the manganese content of the leaves of Star is consistently higher than those of *S*.171 at the lower manganese-levels, but with manganese treatments of 2·0 and 5·0 p.p.m. there is no significant difference. The reverse holds for the manganese content of the roots, as in every case *S*.171 has the higher manganese content, and the difference between Star and *S*.171 is greatest at the highest manganese concentrations. Despite the low levels of manganese obtained in the leaves of both varieties at the 0·0 and 0·1 p.p.m.-levels, no typical grey speck symptoms were observed even in the susceptible variety Star. In contrast, other workers have reported grey speck symptoms associated with leaf concentrations of manganese in excess of those reported[3,9]. Our results are more comparable to those of Lundegårdh, who reported concentrations as low as 1 p.p.m. without grey speck symptoms[10].

In regard to magnesium, the content of the roots shows major varietal differences and an interaction between magnesium and manganese. The variety *S*.171 contains less magnesium in the roots at all levels of manganese than Star, but both varieties show a decrease in magnesium content when the manganese supply changes from limiting to adequate. The difference in the magnesium content of the leaves is not so marked, however, the decrease being most significant in *S*.171.

The relationship to grey speck resistance of high-leaf, low-root manganese content in the susceptible variety Star, and the low-leaf, high-root manganese concentration of the resistant variety *S*.171, is not clear. The analyses are for fully mature plants and may not represent the situation in actively growing material. It is possible that the results represent the effect rather than the cause of varying susceptibility to the grey speck syndrome. It has been established that redistribution of mineral constituents from the shoot occurs during the maturation of oats[11]. Thus, if at maturity manganese passes from shoot to root, then the higher manganese content of the roots and the lower content of the leaves in *S*.171 may reflect the greater mobility of manganese in this variety. The comparative lack of mobility of manganese in Star is then indicated by the high-leaf, low-root manganese concentrations, due to retention of manganese in the leaves without redistribution to the roots. Taking this view, susceptibility to the grey speck syndrome is primarily due to lack of mobility of manganese within the plant.

An alternative is that the mature plant analyses represent the situation in the growing plant, and in this case the grey speck resistance of *S*.171 may be due to the comparatively high concentration of manganese in the roots inhibiting the invasion and multiplication of ammonium-forming rhizosphere organisms, either directly or indirectly through the medium of a root exudate. Resistance to grey speck has been attributed by Gerretsen[6] to the root system having greater resistance to saprophytic organisms. However, more effective mobility of manganese seems more likely to be the basis of superior grey speck resistance, in that the syndrome appears to be primarily a disorder of photosynthesis, with root deterioration as a secondary factor. This is borne out by the rapidity with which deficiency is overcome when manganese-deficient cereals are sprayed with manganese sulphate.

Further work is in progress to determine the relationship of manganese mobility to resistance to grey speck, and the possible interaction of manganese and magnesium.

Dependence on Light of Geotropism in Plant Roots

PLANTS grown in non-porous containers frequently show a lower concentration of roots on the periphery of the block of soil than similar plants grown in porous containers[1], and there is sometimes a tendency for the direction of growth of these peripheral roots to be more nearly vertical in non-porous than in porous containers[2,3]. Gradients of water, nutrient or gas concentration, or of soil temperature, have been suggested as causes of these phenomena, but there is also the possibility that light has an effect, since many non-porous containers made of glass or plastics are transparent, whereas porous 'clay' pots are opaque.

Seeds of China asters (*Callistephus chinensis* var. Ostrich Plume), stocks (*Matthiola incana* var. *annua*), *Calendula officinalis* var. Radio, tomatoes (*Lycopersicon esculentum* var. Amateur) and cucumbers (*Cucumis sativus* var. Market Cross) were sown on July 6, 1960, and transferred to John Innes No. 1 potting compost in the experimental pots on July 15. The pots were of colourless polyethylene, which is highly transparent to all wave-lengths of visible and infra-red radiation, and half of them were made opaque by coating them with black paint, on the outer surface, and on the inner surface down to the level of the soil. Opaque and transparent pots were arranged alternately on a bench in a glasshouse with natural illumination. Three plants of each species and from each kind of pot were examined on July 29 and at intervals of 3–6 days thereafter. An examination consisted in removing the plant from its pot and applying a 'cross of Lorraine' (Fig. 1) marked

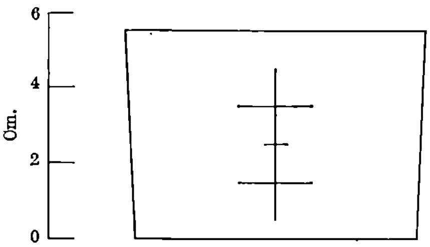

Fig. 1. Side view of a block of soil taken from a pot, with 'cross of Lorraine' superimposed for assessing roots

on a piece of transparent polyvinyl chloride, to four positions taken at random around the nearly vertical wall of the block of soil. In each position, the number of roots intersecting each of the two 2-cm. axes of the upper half of the cross and each of the two 2-cm. axes of the lower half were counted.

For all except tomatoes the increase, from one examination to the next, in the number of intersections counted was greater in the opaque than in the transparent pots. Thus, in order to compare the distributions of roots on the surface of the blocks of soil from the two kinds of pots when the total quantity of root present was much the same in both cases (Fig. 2), it was necessary to relate to the results from the transparent pots, obtained on August 15, corresponding results from opaque pots obtained respectively 16, 14, 6, 3 and 0 days earlier for stocks, calendulas, asters, cucumbers and tomatoes. One of the reasons for a low concentration of roots on the periphery of a block of soil from a transparent nonporous pot therefore appears to be that, for some species at least, light either inhibits the growth of the roots or causes them to turn back into the soil by negative phototropism.

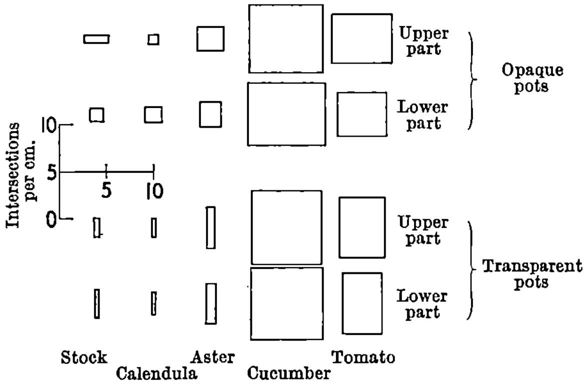

Fig. 2. Distribution of roots on the walls of blocks of soil taken from opaque pots and from transparent pots. The width of a rectangle represents the number of roots intersecting a vertical line and the height represents the number intersecting a horizontal line

Exposure to light influenced not only the concentration of roots but also their direction of growth, which was more nearly vertical in the transparent pots than in the opaque (Fig. 2). The difference was significant ($P<0{\cdot}001$) for all species, except cucumbers. The question arises as to whether this result is accurate or whether disturbing the roots, in order to examine them, had any effect upon the subsequent direction of growth. On August 22, plants of asters, stocks and calendulas which had been examined regularly (five times altogether) were compared with an equal number of plants which had been grown under similar conditions but which had not been disturbed. In opaque pots there was a greater tendency towards vertical growth in the disturbed roots than in the undisturbed of all three species, but the difference was only significant ($P<0{\cdot}01$) for asters (Table 1). For this species there was a similar and significant ($P<0{\cdot}01$) effect of disturbance in transparent pots, so that the result cannot be attributed only to the brief exposure to light at the time of examination, but also to the mechanical effect of taking the block of soil in and out of the pot. The roots in the upper part of the pot were those mainly affected.

Table 1. EFFECT ON THE ROOT SYSTEM OF *Callistephus chinensis* OF REMOVING THE BLOCK OF SOIL FROM THE POT IN ORDER TO EXAMINE IT

Type of pot	Position of roots	$\frac{\text{Intersections of horizontal axis}}{\text{Intersections of vertical axis}}$ Disturbed	Undisturbed
Opaque	Upper part	0·514	0·423
Opaque	Lower part	0·524	0·524
Transparent	Upper part	0·758	0·650
Transparent	Lower part	0·787	0·772

The fact that transparency of the pot wall significantly ($P<0{\cdot}001$) affected the direction of growth of undisturbed roots (Table 1) establishes that the results shown in Fig. 2 cannot be explained by a difference between transparent and opaque pots in the number of times the roots were examined. For tomatoes there was in any event no such difference. The question therefore arises as to whether the downward growth of the roots in transparent pots was a negative phototropism or a light-induced geotropism. The rims of the pots were separated by 8·5 cm. on the glasshouse bench and the polyethylene of the pot walls was somewhat diffusing. The light falling on the roots was therefore coming from many directions, but always with a component into the soil, so that the main effect of phototropism would be a reduction in concentration of roots on the surface and it would only account for vertical growth where re-entry of the root into the soil was prevented. Such a reduction was observed for four species, but not in the case of tomatoes. Since there is no reason to suppose that the roots could not re-enter the soil, one is forced to the conclusion that the vertical growth was a response to gravity.

To confirm this, three plants each of stocks, asters and tomatoes were grown in transparent pots, on a piece of wire netting supported 20 cm. above a reflecting surface of aluminium foil. The pots were enclosed on all sides by a wooden box, and their tops were covered by a piece of foil, blackened on its lower surface and perforated with small holes through which the stems of the plants passed. The arrangement stood in a glasshouse in natural light, which could only reach the roots from below. Root-tips could be seen through the transparent walls of the pots, and their positions were marked without disturbing them. They grew downwards, although this was now definitely towards the light.

Main roots are commonly supposed to exhibit positive geotropism, and lateral roots are sometimes plagiogeotropic although the evidence for this is conflicting[4]. In the present experiment, in the opaque pots there was in no case any evidence for a preponderance of vertical roots ; indeed there was even some evidence for a preponderance of horizontal growth (Table 1 and Fig. 1), especially in the upper part of the pot. In the transparent pots, on the other hand, all the species except cucumber showed a significant tendency towards vertical root growth. Cucumbers commonly produce roots on the surface of the beds in which they are grown commercially.

It now appears that exposure to light is a prerequisite for geotropism in some plant roots. This could be because light is necessary for the formation in the roots of a growth inhibitor, which afterwards becomes asymmetrically disposed under the influence of gravity. The formation of such an inhibitor could also account for the reduction in concentration of roots on the surface of blocks of soil from transparent pots, whereas negative phototropism only does so with difficulty, since roots of stocks, which showed the greatest reduction in concentration, grew towards the light when illuminated from below. The failure of previous investigators to observe a light-dependence of geotropism may be accounted for by their use of very young seedlings, as there may then be sufficient of the necessary growth substance present in the radicle for a geotropic response to take place in the dark.

Mutation for Larger Fruit in the Raspberry

Raspberry breeders have long been concerned with the problem of breeding for larger fruit. Small fruits are a feature of wild raspberries from which present-day varieties are presumed to have been evolved by many generations of selection for improved size of fruit. It is therefore not surprising that size in raspberries is complex in its inheritance, and that breeders find difficulty in combining large fruit with the many other desirable characters required in modern varieties. The discovery of a mutant raspberry with larger fruits might be of importance as a means both of further improvement in this character and, if its inheritance were simple, of simplifying the breeder's task.

Such a mutant has been found in a commercial plantation of the variety Malling Jewel. It is characterized by an overall increase in the length and thickness of the fruiting laterals and the pedicels, enlarged floral parts, and an enlarged receptacle which carries fruit with more drupelets than the parent variety. The drupelets are also larger individually, and contain larger seeds. The laterals appear to develop more slowly, causing the fruit to ripen about 2 wk. later than the normal, but no differences have been found to distinguish the vegetative (first year) growth of the mutant from that of the parent stock.

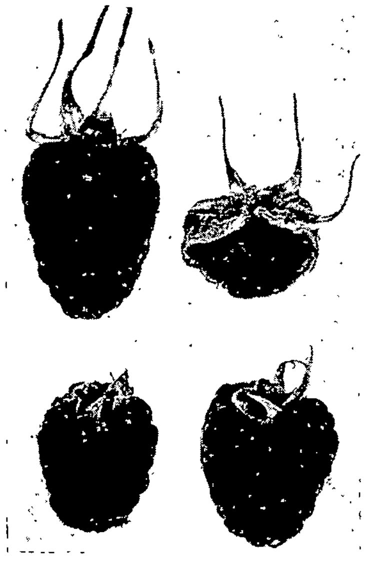

Fig. 1. Fruits of mutant Malling Jewel top left, mutant Malling Promise (top right), normal Malling Jewel (bottom left) and normal Malling Promise (bottom right)

Examination of pollen mother-cells from the mutant showed the normal diploid complement of fourteen chromosomes. Open-pollinated fruits from a plant propagated from the mutant and grown in isolation were used to raise a progeny of 114 seedlings: these all made normal vegetative growth but segregation for mutant types of fruiting lateral was evident in the second year. In addition to forms similar to the parental mutant, more extreme forms occurred which ripened later and had even larger laterals with malformed and frequently with sterile flowers. Classification of the seedlings gave normal, mutant and extreme mutant forms in the ratio of 40 : 56 : 18. This does not depart significantly from the expectation if the mutation were caused by a change in a major gene from the homozygous to the heterozygous state, and if the latter were intermediate in expression.

It seems that the change causes an error in the development of the axillary meristems, resulting in enlargement of all the tissues derived from them. The manifold effects of the gene are probably the result of what Grüneberg[1] has termed 'spurious' pleiotropism. Certain of these effects, such as the increase in seed size, are undesirable, but the growth of fruiting laterals in raspberries is governed by many minor gene complexes which give considerable independent variability to each component part. It is probable that the faults could be corrected by selection for these minor genes, for example by selecting for small seeds after crossing the mutant with a small-seeded variety such as Baumforth's Seedling *B*.

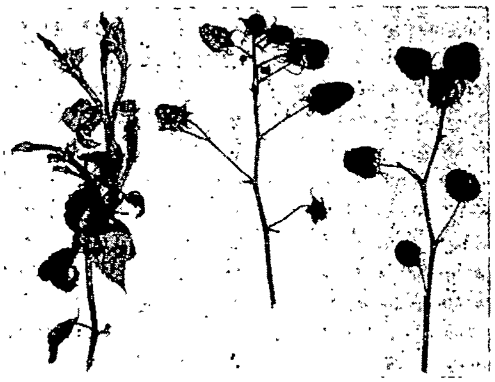

Fig. 2. Three forms of fruiting lateral which occurred in the progeny of mutant Malling Jewel: extreme, parental and normal

A second mutant raspberry has been found in a plantation of Malling Promise, but this mutant more closely resembles the extreme and presumably homozygous forms which segregated from the Malling Jewel mutant. It is conceivable that the same mutant gene may be more dominant in some genic backgrounds and may produce these sub-fertile forms when it is heterozygous ; alternatively the Malling Promise form may be a higher allele. An investigation is being made of the interactions of the mutant gene with different minor gene complexes to clarify these questions.

I am indebted to Mr. J. Morrison, of Forfar, Angus, for directing my attention to these mutants in 1958 and 1959, and to Miss N. N. Tun for counting the chromosomes.

Growth of Ryegrass-dominant Pasture grazed by Cows, and Properties of New Zealand Butterfat

MARKED and regularly recurring seasonal fluctuations in the characteristics of New Zealand butterfat have been reported by Cox and McDowall[1]. The iodine value, for example, rises to a maximum of about 41 in mid-winter, falls gradually until the beginning of October and then rapidly during October and November to a mid-summer minimum of about 34, and rises again during the autumn and early winter to the mid-winter maximum. The carotene and vitamin *A* contents of the butterfat also have been shown by McDowell and McDowall[2] to change according to a regular seasonal pattern, with maximum values in the early spring and minimum values in mid-summer. These latter changes have been found by McGillivray[3] to be a reflexion of changes in the carotene and vitamin *A* contents of the blood plasma.

Seasonal changes in the properties of butterfat resulting from alternations between stall and pasture feeding of the cows, or from changes in the type of feeds given to stall-fed cows, have been reported by numerous investigators overseas, but it was surprising to find changes of this magnitude in the butterfat and blood plasma of cows grazing throughout the year on open pasture according to the general New Zealand practice. The causes of these changes have not hitherto been established.

In New Zealand almost all cows supplying the dairy manufacturing industry are calved down in the early spring. There are therefore consistent changes in the stage of lactation of the cows with progress of the dairying season, both for successive dairying seasons and for the different dairying districts. It is then a facile inference that the changes in butterfat properties are associated with change in the stage of lactation of the cows. In an investigation at this Institute with monozygous twin cows separated by several months in calving date, however, the butterfat from the later calving cow of each pair of twins was similar in properties to that from the earlier calving cow after the normal immediate post-parturition changes had been completed.

The indications were, therefore, that the changes in butterfat properties resulted from changes in the nature of the feed consumed by the cows, that is, changes in the character of the pastures. In this connexion it seemed significant that the sudden change in properties of butterfat in October–November is coincident with the rapid expansion in growth of clover in the clover-ryegrass associations, typical of most dairy pastures in New Zealand.

A change from ryegrass-dominant to clover-dominant pasture has been found by Worker and McGillivray[4] to cause some decrease in vitamin content of the butterfat, but the effect was relatively small and somewhat irregular. Further trials in which ryegrass and white clover were fed separately to twin cows have indicated that the effect of the sudden increase in the proportion of clover in the pasture consumed by cows is not sufficient to account for the observed changes in the characteristics of the butterfat.

At the same time as the proportion of clover in the mixed pasture shows a rapid increase, there is, during October–November, a transition in character of the ryegrass from the early spring lush soft foliage to the somewhat harder and more fibrous foliage which develops as the grass matures. Pure stands of *H*1 short rotation ryegrass were therefore prepared, for an investigation of the effect of maturity of ryegrass in the pasture on the butterfat properties. Portions of the area were kept closely grazed, so that the leaves were short (3–4 in.) and succulent, and the grass on the remainder of the area was allowed to grow to a height of approximately 12 in., at which stage the stalks were firming and becoming somewhat fibrous. Cows from a number of monozygous twin pairs were grazed on the two areas during September–December. Throughout this period it was found that the butterfat from the cows on the young leaves had the properties of normal early spring New Zealand butterfat, whereas that from the cows grazed on the longer-stemmed ryegrass had the properties and the carotene and vitamin *A* contents of normal October–November New Zealand butterfat. There were similar differences in the carotenoid contents of the bloods of the two groups of cows. The differences were maintained over the whole period of feeding of the two types of pasture. The average results given in Table 1 cover the period during which more detailed investigations of the fatty acid composition of both grass lipid and butterfat were made. Although the fats from both types of pasture were highly

Table 1. AVERAGE ANALYTICAL RESULTS FOR GRASS, GRASS LIPIDS, BLOOD AND BUTTERFAT FOR THE TWO TREATMENTS DURING SEPTEMBER 25–OCTOBER 6

Product analysed	Substance estimated	Average results		Difference (*I*)–(*M*)
		Immature grass (*I*)	Mature grass (*M*)	
Grass	Carotene (μgm./gm. dry matter)	545	400	145
	Lipid content (mgm./gm. dry matter)	86	46	40
Grass lipid	Linolenic acid (moles per cent)	62·0	53·0	9·0
Blood	Carotene (μgm./ml.)	21	15	6
Butterfat	Carotene (μgm./gm.)	11·5	10·3	1·2
	Vitamin *A* (μgm./gm.)	10·6	8·1	2·5
	Iodine value	43·2	35·6	7·6
	Oleic acid (moles per cent)	34·3	30·5	3·8
	Linoleic acid (moles per cent)	3·3	1·8	1·5
	Linolenic acid (moles per cent)	1·5	1·0	0·5

unsaturated, those from the immature pastures contained a higher proportion of unsaturated acids than those from the mature pastures. There was also a higher proportion of fat in the immature pasture. The differences in properties of the butterfats from cows grazing on the two types of pasture were thus associated with differences in both the nature and the amount of lipids present. It would seem, therefore, that the composition of butterfat from pasture-fed cows is markedly influenced by the type of pasture consumed, and that the seasonal changes in the carotene content of the blood and in the composition and properties of the butterfat from cows grazing typical New Zealand pastures result from seasonal changes in the state of maturity of the ryegrass in the pasture.

Intra-ovarian Pollination in *Eschscholzia californica* Cham., *Argemone mexicana* L. and *A. ochroleuca* Sweet

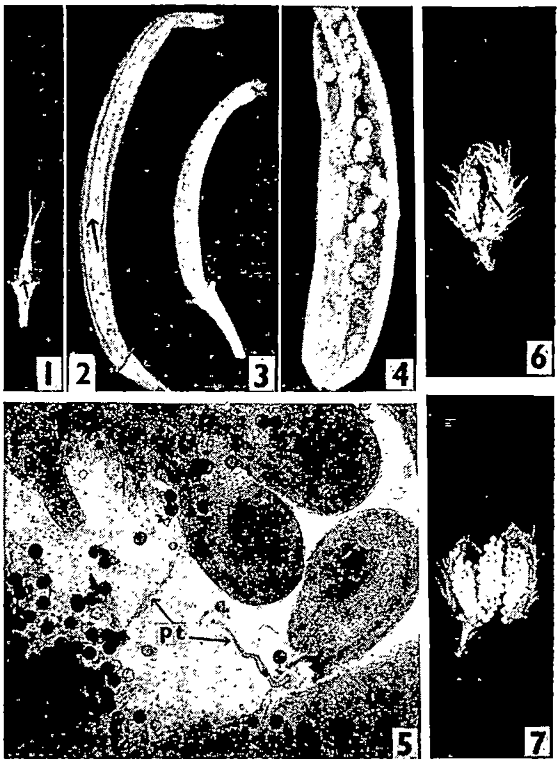
In an earlier communication one of us[1] described the results of intra-ovarian pollination in *Papaver rhoeas*. The present work deals with some observations of a similar nature on *Eschscholzia californica*, *Argemone mexicana* and *A. ochroleuca*.

The pollen suspensions were prepared in 0·5 c.c. of a boric acid solution—200 mgm./l. for *Eschscholzia* and 100 mgm./l. for *Argemone*. Each drop of the suspension contained 200–300 pollen grains.

Eschscholzia. The ovaries injected with pollen suspension grew normally (Figs. 1–3) although the size of the fruits was smaller than that of fruits from naturally pollinated ovaries.

The pollen grains germinated in the ovarian cavity (Fig. 5) and many pollen tubes entered the ovules. The growth of the fertilized ovules was slow in the beginning but the ultimate size (Fig. 4) attained by them was equal to that of ovules from naturally pollinated ovaries. The maturation of the ovaries and dehiscence of the capsules resulting from intra-ovarian pollination took almost the same time as in Nature (25–30 days). The seeds were viable and the embryos as large or larger than those which developed naturally. The seeds germinated and gave rise to normally flowering and fruiting plants.

Argemone. When a pollen suspension in 100 mgm./l. boric acid was injected the germination of the pollen grains inside the ovarian cavity was very low and scarcely more than 1 or 2 seeds were produced per fruit, or sometimes none at all. If a suspension of the pollen grains in double distilled water was used, seed setting was slightly improved (2–4 per fruit). However, when the pollen grains were introduced as such into the ovary through a vertical slit, they germinated profusely (50 per cent) and the seed set was very high. In *A. ochroleuca* about 60 seeds (Figs. 6, 7) and in *A. mexicana* as many as 140 seeds were produced per fruit ; in Nature the number of seeds varies between 150 and 200 in the two species.



Figs. 1–5. *Eschscholzia californica*, ovaries injected with a suspension of pollen in 200 mgm./l. boric acid. Fig. 1. Ovary at the time of anthesis and injection of pollen grains; the arrow in this and in Fig. 2 indicates the place of injection of the pollen suspension (× $\frac{3}{4}$). Figs. 2 and 3. 17 and 25 days after injection (× $\frac{3}{8}$). Fig. 4. Same as Fig. 3, cut vertically to show the developing ovules (× 2·25). Fig. 5. Transverse section of ovary 72 hr. after injection; note the pollen tubes (*pt*) from the germinating pollen grains in the ovarian cavity (× 47). Fig. 6. *Argemone ochroleuca*, ovary 12 days after insertion of pollen through a vertical slit shown by an arrow (× $\frac{3}{8}$). Fig. 7. Same as Fig. 6, split open to show developing ovules (× $\frac{3}{8}$)

In *A. mexicana* the growth of treated ovaries was slow and the maximum size attained by them was only two-thirds of the normal. In *A. ochroleuca* the treated ovaries grew to less than one-half of their natural size. Nevertheless, in both the species the growth of the ovules and the differentiation of the embryo were almost similar in the treated as well as in the naturally pollinated ovaries. The capsules ripened and dehisced in the same period (27–30 days after anthesis) in both sets and the seeds obtained by intra-ovarian pollinations were fully viable.

A. mexicana is a diploid ($n = 14$) and *A. ochroleuca* a tetraploid ($n = 28$)[2,3]. Natural hybrids between the two are rare and usually sterile[2]. This incompatibility could possibly be overcome by intra-ovarian pollination and work in this direction is in progress. The technique of injecting pollen grains into the ovary may be of help in overcoming some types of incompatibilities.

CYTOLOGY

Periodic Acid–Schiff Positive Giant Cells in the Mouse Thymus Cortex

HAMMAR[1] first described cells, laden with fat granules, in the thymus cortex of ageing humans. More recently, a detailed description of the histochemical reactions of these cells in the mouse thymus has been given by Loewenthal and Smith[2], who pointed out that these cells gave a strong red colour when stained with the periodic acid–Schiff reagent (PAS).

During a survey of the morphology of the thymus in high- and low-leukæmia strain mice, these cells were observed in large numbers in the cortices of ageing *AKR* and *C3H* mice. Their nuclei resembled thymic reticulum cell nuclei rather than those of the lymphocyte series. The cytoplasm of these cells was voluminous, and packed with granular material with the following staining reactions: positive to PAS (diastase resistant), pyronine and scharlach *R*; negative to toluidine blue (stained pale green), eosin and Feulgen. The cells appeared capable of phagocytosis, since they frequently contained pyknotic nuclear material, presumably lymphocytic in origin. These cells first appeared in the thymus in mice aged between two and four months, and their number increased with advancing age, although varying considerably in individual thymuses. These cells were found in increased numbers in thymuses of mice in the second half of pregnancy, if aged older than four months. The development of these PAS cells appeared to be related to changes in age of cellular elements within the thymus itself. One-week-old thymuses were grafted subcutaneously into six-month-old *C3H* mice and examined histologically one month after grafting. Although all host thymuses showed numerous PAS cells, none of the grafted thymuses showed such cells. Similar negative results were obtained with week-old thymuses grafted to pregnant six-month-old *AKR* hosts. These results appear to exclude the possibility that circulating humoral factors in ageing mice are primarily responsible for the development of these cells.

The location of the PAS cells was usually subcapsular, but frequently they were scattered uniformly throughout the cortex. The cells were not uniform in size and varied from 7μ to 26μ in diameter. The mean size of the cells increased progressively with advancing age. The PAS cells were surrounded by tightly packed lymphocytes. Frequently lymphocytes were seen which had invaginated the cytoplasm of the PAS cells and were lying in deep crypts, projecting into the cells.

In 7μ sections, one in three PAS cells was observed to have one or more mitotic lymphoid cells in contact with some part of the cytoplasm of the cell. A quantitative analysis was made of the frequency of mitotic lymphoid cells in the area surrounding PAS cells, relative to areas distant from these cells. In each thymus, twelve fields, $72\mu \times 72\mu$, were selected at random and drawn on graph paper and the total PAS area determined (area of PAS cells, plus area 5μ in width around each cell). Cortical tissue outside this area was designated 'non-PAS' area. The number of mitoses in both areas was determined and the stage of each mitosis noted. The results (Table 1) indicated that, in *AKR* thymuses, mitoses per unit area were three times more frequent in the PAS areas than in the adjacent 'non-PAS' areas. The results in thymuses of the low-leukæmia strain *C3H* indicated much less difference in the incidence of mitoses between the two areas. These results require extension to confirm the reality of this difference in strain.

Table 1

Strain	Age (months)	Sex	No. of thymuses	Mean percentage PAS area	Mean mitoses in PAS area, per unit area	Mean mitoses in 'non-PAS' area, per unit area	Ratio PAS mitoses 'non-PAS' mitoses*
AKR	6–10	M	13	27	95	32	3·1 ± 0·8
AKR	6–8	F	10	21	73	26	3·0 ± 0·8
C3H	8–10	M	12	24	59	42	1·4 ± 0·4

* ± *S.D.*

The analysis of the percentage of cells in various stages of mitosis in the two areas revealed, in *AKR* thymuses, a predominance of prophase mitoses in the PAS areas (11 ± 4 per cent versus 6 ± 3 per cent in the 'non-PAS' areas). The percentages of the other stages of mitosis were similar in both areas.

The significance of the association between lymphocyte mitotic activity and PAS cells in the thymus cortex is not known. The PAS cells may either stimulate mitosis in neighbouring lymphoid cells, or may attract cells about to enter mitosis. The predominance of prophase mitoses around PAS cells suggests that such stimulation or attraction may be related to the initial phases of mitosis, and that some of the mitotic cells may later move away from the PAS cells before mitosis is complete.

Since the PAS cells and associated mitoses occur only in post-involutional thymuses, they may represent some type of regulation of thymic lymphocyte mitotic activity, supervening on an earlier form of regulation present in the pre-involutional thymus.

VIROLOGY

A Method of treating Asbestos Filter Pads for Virus Filtration

PRE-TREATMENT of Seitz-type filters with serum or with digest broth will reduce, to some extent, the often serious losses of virus caused by adsorption during filtration. Solutions of gelatin have been used recently instead of serum or broth with the same object in view. Although certain advantages are claimed for the use of gelatin, for example that most samples are antigenically inert, experience has shown that losses during filtration through asbestos filters treated with this protein substance are not uniformly negligible.

For some purposes it is desirable to avoid the addition of foreign protein to virus preparations, and so investigations were made to determine whether non-protein substances of complex molecular structure would diminish the virus-adsorbing properties of asbestos filter pads.

Sodium alginate, the sodium salt of alginic acid $(C_6H_8O_6)_n$, a polymer of beta-D-mannuronic acid, which is generally considered to be a non-protein substance, was used for this purpose and its efficacy was compared with that of gelatin. It is as well to mention, however, that protein estimations by the Folin-Ciocalta method revealed that the particular preparation used in these experiments contained a trace of protein (0·16 per cent calculated for dry weight). This protein no doubt occurred as an impurity and originated from the seaweed *Laminaria cloustoni*, from which the alginate was prepared. The concentration of protein in the 0·04–0·05 per cent solutions finally recommended for treatment of filter pads would be only 0·0006–0·0008 per cent. The effect of the alginate solution is attributable, therefore, principally to the complex polysaccharide molecule of alginic acid, in which the mannuronic acid units are connected in long chains by 1,4-β-glycosidic linkages.

Asbestos filter pads were treated before use with 25·0 ml. of solutions containing concentrations of either sodium alginate or gelatin in the range 0·0025–0·06 per cent; excess solution was then washed from the pads by passing 50·0 ml. of *M*/25 phosphate buffer through them. Untreated control pads were washed with 75·0 ml. of buffer only, to adjust the *p*H of the pad.

Preparation of viruses. The virus suspensions used in the experiments were first passed through clarifying filters to remove gross particulate matter. The results obtained therefore refer to relatively crude preparations and not necessarily to highly purified virus.

For all experiments on the virus of vesicular stomatitis, an egg-passaged strain of Indiana type (Ind. *C*.) was used, manipulations being performed with appropriate precautions to avoid inactivation by light[1]. The virus suspensions in physiological saline were made from embryo extracts.

Strains of foot-and-mouth disease virus of types *O*, *C* and Asia 1 were propagated in serum-free pig kidney or tongue epithelium tissue culture; culture extracts were diluted in *M*/25 phosphate buffer before filtration.

Filters. Asbestos filter pads of 3·0 cm. diameter were used throughout the series of experiments; all were of *E.K.* equivalent grade (Ford *G.S.* or Seitzwerke *E.K.*). Solutions of gelatin were made by dissolving gelatin powder (British Drug Houses, Ltd., Poole, Dorset) in warm distilled water, and then diluting the solution to give the required concentration of gelatin. The sodium alginate used in all experiments was of pharmaceutical grade and conformed with the *British Pharmaceutical Codex* specification. The following analytical data were kindly supplied by the makers (Messrs. Alginate Industries, Ltd., Bedford Street, London, W.C.2):

Moisture content		20·4 per cent
Calcium content		0·27 per cent
Lead content	(less than)	10 p.p.m.
*p*H		6·3
Viscosity of 1 per cent solution*		62 centi-stokes

* Measured in a B.S. U-tube viscometer at 25° C. and corrected for moisture content of the powder.

The calculated mean molecular weight was approximately 88,000; somewhat greater than that of serum albumins (65,400–72,300 when calculated from sedimentation and diffusion constants[2]).

Stock solutions of sodium alginate in glass-distilled water were prepared at a concentration of 0·05 or 0·1 per cent w/v, and these solutions were diluted for use as required. Residual solutions were always discarded seven days after preparation.

Mice. Samples of vesicular stomatitis virus were titrated in 8-day old mice of the Pirbright '*P*' strain; 4–6-day old mice of the same strain were used for titrations of the foot-and-mouth disease virus.

Titrations were made in groups of 8 or, occasionally, 6 mice per dilution with either 0·6 or 0·5 log intervals between dilutions of each series. The dose was 0·03 ml. for both virus systems, but inoculations were made intracerebrally with vesicular stomatitis virus and intraperitoneally with foot-and-mouth disease virus.

Calculation of results. The 50 per cent fatality end-point for each series was estimated by the Spearman–Kärber method to permit determination of the amount of virus lost during filtration.

The results obtained with suspensions of vesicular stomatitis virus before and after filtration are given in Fig. 1. They show that when filters are merely washed with *M*/25 phosphate buffer, to prevent inactivation of virus by *p*H changes while passing through the filter, the losses of virus during filtration in some cases exceeded 5 log units.

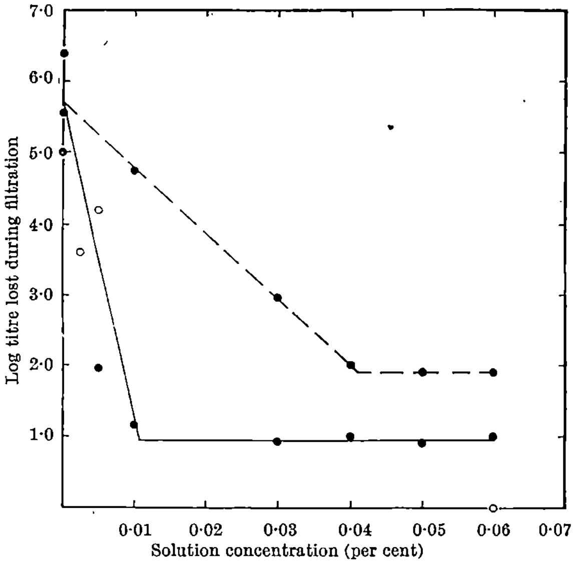

Fig. 1. Filtration of vesicular stomatitis virus through treated asbestos filters. Ford *G.S.* filter, ●; Seitz *E.K.* filter, ○; sodium alginate solution, ——; gelatin solution, – – –

Pre-treatment of filters with increasing concentrations of either gelatin or sodium alginate progressively decreased the losses of virus up to a finite value for each substance; but thereafter further increments of gelatin or sodium alginate in the solution failed to reduce filtration losses below the critical values of 1·95 and 0·9 log units, respectively. Losses in gelatin-treated filters were always greater than losses in filters treated with the same concentration of sodium alginate (Fig. 1).

When foot-and-mouth disease virus was filtered through either treated or untreated filters, the adsorption losses were considerably less than those encountered during filtration of vesicular stomatitis virus. This difference is probably a function of virus size, the

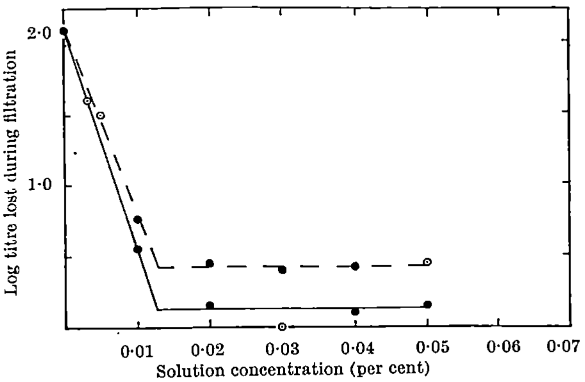

Fig. 2. Filtration of foot-and-mouth disease virus through treated asbestos filters. Mean values, ●; single values, ⊙; sodium alginate solution, ——; gelatin solution, - - -

infective component of the former virus being a roughly spherical particle 20–25 mμ in diameter, whereas that of the latter virus is a short rod-shaped body having an effective filtration diameter of 80–100 mμ. Nevertheless, more virus was lost in pads treated with gelatin solutions than in the corresponding pads of the sodium alginate series (Fig. 2). Irrespective of the concentrations used, it was impossible to reduce the filtration losses to less than about 0·15 log unit with sodium alginate or 0·43 log unit with gelatin.

These observations, together with the apparent inability of sodium alginate to act as an antigen, indicate that pre-treatment of asbestos filter pads with 0·04–0·05 per cent solutions of sodium alginate is a valuable means of minimizing adsorption losses during filtration of virus suspensions. The inferior results obtained with the protein, gelatin, may justify attribution of this effect to the sodium alginate *per se*, and not to the presence of infinitesimal amounts of protein impurity in the solutions used for treatment of the filters.

I am indebted to Dr. F. Brown for the protein estimations.

SOIL SCIENCE

Factors influencing the Composition of the Cellulose-decomposing Microflora on Soil Crumb Plates

Although many soil micro-organisms can decompose cellulose[1], each group of organisms does so under its own set of conditions. For example, *Cellvibrio* and *Cytophaga* develop around soil crumbs placed on filter paper which covers a mineral silica-gel medium, as shown by Winogradsky[2]. Other workers have reported that cellulose-decomposing fungi were the first organisms to attack 'Cellophane' buried in the soil[3].

It was sought to determine what causes one or the other species of the cellulose-decomposing flora to predominate and whether this is due to differences in technique or in the cellulose substrate used. For this purpose the composition of the cellulose-decomposing soil flora on filter paper and on 'Cellophane' were compared under the same conditions. Strips of filter paper (Whatman No. 1) and strips of 'Cellophane' (*PT* 300, British Cellophane Co.) were placed on mineral agar solidified in Petri dishes. Soil crumbs taken from the same soil sample were spread on strips of filter paper and 'Cellophane', respectively, and the Petri dishes were incubated for a few days at 30°.

Bacteria only (mostly *Cellvibrio*) developed on the plates covered with filter paper, while cellulose-decomposing fungi (mostly *Stachybotrys*) predominated on 'Cellophane' plates.

The failure of *Stachybotrys* to appear around soil crumbs on the filter paper could not be explained by its inability to attack the substrate, because a pure culture of *Stachybotrys* grew well on filter paper. To elucidate this question, the possibility of the bacterial growth interfering with the fungal growth was investigated. Soil crumbs were spread on filter paper placed on mineral agar plates containing 100 μgm./ml. chloramphenicol to inhibit bacterial growth, when only cellulose-decomposing fungi, especially *Stachybotrys*, developed.

In further tests a pure culture of *Stachybotrys* spores was mixed with a pure culture of *Cellvibrio* and the mixture inoculated on strips of filter paper on mineral agar. Under these conditions *Stachybotrys* failed to develop, or grew poorly, demonstrating the strong inhibitory effect of *Cellvibrio*.

Dobbs and Hinson[4] show that soil has a strong inhibitory effect on the germination of fungal spores; thus it was of interest to see whether *Cellvibrio* inhibited the germination of *Stachybotrys* spores. Direct microscopic observations of *Stachybotrys* spores in the presence of *Cellvibrio* showed that, although the spores germinated normally, growth was arrested after the development of the germination tubes. *Cellvibrio* inhibited the growth of the fungus only on media containing cellulose as the sole carbon source, and not when glucose or cellobiose was present.

No filtrable or diffusible substances responsible for the antagonism were detected. Direct contact between both organisms seems to be necessary to get the effect.

The predominance of fungi in the flora of soil crumbs spread on 'Cellophane' could easily be explained when it was shown that a pure culture of *Cellvibrio* either failed to grow, or grew only slightly, when 'Cellophane' was used as the substrate.

'Cellophane' has been much used recently in investigations of the cellulose-decomposing soil flora[3]. It is therefore important to point out that this substrate does not equally support the development of all the cellulose-decomposing micro-organisms, but seems to be more of an enrichment medium for the selection of cellulose-decomposing fungi.

PSYCHOLOGY

Learning in Two Sense-modalities

In previous investigations[1,2] monkeys were taught to discriminate between shapes or rates of intermittence exclusively in one sensory modality (say visual) and were afterwards tested with the same shapes or rates exclusively in another modality (say tactile for shapes or auditory for rates). There was no evidence of cross-modal transfer of training. A variation of this procedure was also briefly described[1]. Four animals first learnt to discriminate between two test objects exclusively by touch (in the dark) and were afterwards tested for 30 trials with the same objects (in the light) under conditions where the objects could be discriminated either by touch or by vision. Only one animal performed significantly better than chance in the light. It was concluded that "even when monkeys are constrained to touch the very cues which served as the basis for successful somato-sensory discrimination of shape or size on the preceding day, there is still no clear indication of positive transfer on visual testing" (p. 62). In the present investigation the converse procedure was used: animals were first trained to discriminate between test objects by vision and/or touch (in the light) and were afterwards tested with the same objects for discrimination by touch alone (in the dark).

Three separate batches of respectively 8, 6 and 7 untrained rhesus monkeys (weight-range, 3·3–6·3 lb.) formed the three groups of subjects. All the subjects in a group were trained concurrently and all training was carried out under comparable conditions by the same investigator. However, group I animals were trained during March, group II during July and group III during November. (This consecutive training was necessary because all animals afterwards took part in different experiments.)

Standard apparatus (Wisconsin general testing apparatus) was used in conjunction with two food boxes placed 12 in. apart. The test objects were fastened to the lids of these boxes. Forty trials (non-correction) were given each day with the right/left positions of the positive test objects determined by the Gellerman schedule. During tactile training (in the dark) the animals' performance was observed by means of an infra-red telescope.

Animals of group I were first taught (see Table 1) to discriminate in the light between two relatively unsaturated hues, pink and cream. Animals of groups II and III were first trained on a quality discrimination in the light. In this test the positive (rewarded) object consisted of a piece of black foam rubber (2 × 0·75 × 0·3 in.) attached across the lid by a steel strip and two bolts. The negative object consisted of a black piece of wood of nearly the same dimensions as the rubber (but of different texture). The lids could only be opened by grasping and then pushing either the rubber or the wood. For their second test all 21 animals were trained to make this quality discrimination in the dark. However, animals of group III were concurrently given a further 100 trials on the visual form of this test according to a method described elsewhere[3]: visual trials in the light alternated with tactile trials in the dark (making 20 visual and 20 tactile trials each day), but were excluded from the learning scores relating to the tactile form of the test.

Table 1. Training Histories and Results on Quality Discrimination Test

Group I ($n = 8$)	Group II ($n = 6$)	Group III ($n = 7$)
Visual hue discrimination Mean = 275 trials	Quality discrimination (in the light) Mean = 192 trials	
Tactile quality discrimination test (in the dark)		
Animal: (1) 137 trials	93 trials	85 trials
(2) 162 „	116 „	55 „
(3) 133 „	98 „	243 „
(4) 157 „	97 „	43 „
(5) 60 „	84 „	318 „
(6) 108 „	120 „	46 „
(7) 124 „		62 „
(8) 161 „		

The figures refer to the number of trials required to reach the standard level of performance (10 or less errors in 100 consecutive trials).

Table 1 contains the results for the tactile test. There is considerable overlap between the scores of animals belonging to different groups. Animals of group I tended to have the highest scores and animals of group III, with two exceptions, tended to have the lowest scores. These two animals, although extremely hesitant and unresponsive on this their first tactile test, have not been excluded because on subsequent tactile testing their performance fell within the range relating to other animals. Statistical comparisons (Mann-Whitney '*U*' test) indicate a significant difference between the scores of group I and group II animals ($P = 0·02$); but not between the scores of group I and group III animals ($P = 0·14$) or between those of group II and group III animals ($P = 0·15$).

These results indicate that in the monkey combined visual and tactile experience of two objects may lead to significantly improved performance (group II animals) when the same objects are afterwards offered for exclusively tactile discrimination. A comparable investigation has not been found in the literature. There are at least three interpretations of the present results. First, since cross-modal transfer from vision to touch could not be demonstrated in a previous investigation[1] it is unlikely that memory of the actual visual quality discrimination improved the performance of the group II animals during later tactile testing in the dark. Secondly, non-specific familiarity with the test objects, acquired during training in the light, may have accelerated subsequent tactile learning. Thirdly, it is possible that obligatory tactile contact with the objects during testing in the light led to some measure of genuine tactile discrimination learning. Irrespective of its origin, this improvement in tactile learning resulting from visual-tactile experience of the test objects in the light was not as pronounced, at least under the present experimental conditions, as might have been expected.

This work was supported by the Research Fund of the Institute of Neurology and by the Medical Research Council. Dr. E. A. Carmichael gave it his active encouragement and provided facilities, as did Dr. E. T. O. Slater. I am also much indebted to Dr. S. L. Chorover for help with the preparation of this communication.

G. Ettlinger

Psychological Laboratory,
Institute of Neurology,

FORTHCOMING EVENTS

Tuesday, July 18

Council for the Preservation of Rural England (at the Royal Institute of British Architects, 66 Portland Place, London, W.1), at 2.30 p.m.—Annual General Meeting. Mr. Harold Abrahams, C.B.E.: "The Amenity Societies, the National Parks Commission and their Common Cause".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant, Grade "B" (with a good honours degree, together with some research, industrial or teaching experience, and preferably a knowledge of some branch of modern applied mathematics such as operation research, numerical analysis or electronic computers) in Mathematics—The Principal, Brunel College of Technology, Woodlands Avenue, Acton, London, W.3 (July 19).

Lecturer (Grade II) or Assistant Lecturer (Grade III) in Clinical Pathology in the Department of Veterinary Medicine at the School of Veterinary Science, Langford—The Registrar and Secretary, The University, Bristol (July 19).

Research Sociologist in the Department of Nutrition, for an investigation of social factors affecting nutrition—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8 (July 19).

Lecturer or Assistant Lecturer (graduate with an interest in the philosophy of science) in Philosophy—The Registrar, The University, Leicester (July 20).

Assistant, Assistant Experimental Officer grade (preferably with a degree and some knowledge of languages), with the Agricultural Research Council's Weed Research Organization, near Oxford, for duties which include abstracting, indexing and responsibility for the Organization's Library—The Secretary, Agricultural Research Council, Weed Research Organization, Begbroke Hill, Sandy Lane, Kidlington, Oxford (July 22).

Computer Officer (graduate) in the Sub-Department of Numerical Analysis—The Registrar, The University, Liverpool (July 22).

Graduate (with a degree in biochemistry or related subjects), to take part in a chemical and biochemical investigation concerned with fruits and vegetables—The Director, Low Temperature Research Station, A.R.C., Downing Street, Cambridge (July 22).

Lecturer or Junior Lecturer (with a postgraduate degree in biochemistry and some teaching experience) in the Department of Biochemistry—The Secretary, The London Hospital Medical College, Turner Street, London, E.1 (July 22).

Lecturers (preferably with research and/or industrial experience) in Physical Chemistry—The Principal, Nottingham and District Technical College, Nottingham (July 22).

Research Assistant (graduate in science, preferably physics, and with a knowledge of electronics), for investigations into the measurement of radioactivity in livestock—The Registrar, The University, Leeds 2 (July 22).

Research Assistant in the Department of Geology, to collaborate in field and laboratory studies of Irish Dalradian rocks—The Registrar, The University, Liverpool (July 22).

Scientific Officer or Senior Scientific Officer (with a good honours degree, and preferably some postgraduate experience), to work on biochemical processes in seeds and seedlings—The Secretary, National Vegetable Research Station, Wellesbourne, Warwick (July 22).

Temporary Lecturer in Pure Mathematics—The Registrar, University College, Singleton Park, Swansea (July 22).

Research Student in X-Ray Crystallography, to work for a higher degree under the supervision of Dr. S. C. Nyburg on crystal structures and absorption spectra of transition metal complexes—The Registrar, University College of North Staffordshire, Keele, Staffs (July 28).

Scientific Officer, Senior Scientific Officer or Principal Scientific Officer (suitably qualified scientist, preferably with experience of blood grouping or serology), to extend the work of the Organization on antigens and biochemical variants in cattle blood—The Secretary, Animal Breeding Research Organization, Glenbourne, South Oswald Road, Edinburgh 9 (July 29).

Lecturer (medical or honours science graduate, with experience in general microbiology or microbial chemistry, and in research methods) in Bacteriology—The Secretary, The University, Edinburgh (July 31).

Lecturer or Senior Lecturer (preferably with a special interest and experience in dairy husbandry and postgraduate experience in animal physiology) in the Department of Agriculture—The Registrar, The University, Leeds 2 (July 31).

Plant Physiologist, Scientific Officer grade (with an honours degree and preferably postgraduate experience), to work on light intensity and leaf canopy development in orchards in relation to tree form and its modification for high yield—The Secretary, East Malling Research Station, Maidstone, Kent (August 1).

Postdoctoral Fellow in the Department of Chemistry, to work on mould metabolites—Prof. R. A. Raphael, Department of Chemistry, The University, Glasgow, W.2 (August 1).

Senior Technician in the Department of Agriculture, University College, Ibadan, Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 4).

Lecturer or Assistant Lecturer in Zoology (Entomology) at the University College of The West Indies—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 7).

Technician (qualified and experienced draughtsman, preferably with photographic experience) in the Department of Geography, University College, Ibadan, Nigeria, for work involving the preparation of maps for display and publication—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 12).

Senior Research Assistants and Research Assistants in Fluids Mechanics—Prof. K. Stewartson, Science Department, The University, South Road, Durham (August 15).

Chair of Pathology in Makerere University College, East Africa—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 20).

Chair of Physics at Fourah Bay College, University College of Sierra Leone—The Secretary Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 31).

Lecturer (with an honours or higher degree in chemical engineering or equivalent qualifications, and preferably an interest in mass transfer or nuclear chemical engineering) in Chemical Engineering at the University of Canterbury, New Zealand—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, August 31).

Lecturers (3) (with special qualifications in inorganic, organic or physical chemistry) in Chemistry at the University of Canterbury, Christchurch, New Zealand—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1, or The Registrar, University of Canterbury (New Zealand and London, August 31).

Scientific Officer (honours graduate with a special interest in plant breeding and genetics), for work on tree fruits under experienced leadership, as one of a team of fruit breeders—The Secretary, East Malling Research Station, Maidstone, Kent (August 31).

Scientific Officer (honours graduate), for research on problems arising out of the vegetative propagation of fruit plants—The Secretary, East Malling Research Station, Maidstone, Kent (September 30).

Assistant Lecturer (with a good honours degree, and preferably research and/or industrial experience) in Physical Chemistry—The Registrar, Hatfield College of Technology, Hatfield, Herts.

Assistant Professor (with Ph.D. or equivalent, and preferably with a background and experience in marine biology) of Biology, to give instruction primarily in animal physiology—Head, Department of Biology, Memorial University of Newfoundland, St. John's, Newfoundland, Canada.

Chemist (with an honours degree in agricultural chemistry or chemistry, and preferably at least one years postgraduate training at an experimental station) in the Department of Agriculture, Uganda, for research work on soil fertility problems connected with tropical crop rotations, manures and fertilizers—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.63/9/09/C1.

Chemist (with some research experience in physics or biochemistry), to work on certain aspects of the chemistry of wheat protein; and an Assistant (male, with some experience in the management of laboratory animals), for a small animal unit concerned mainly with nutritional research on flour and bread—The Director of Research, Cereals Research Station, Old London Road, St. Albans, Herts.

Graduate (preferably with previous experience in tissue culture or virology), to be responsible for the maintenance and supply of tissue cultures needed for research on trachoma and related eye diseases—Dr. L. H. Collier, Trachoma Research Unit, Lister Institute, Chelsea Bridge Road, London, S.W.1.

Lecturer or Assistant Lecturer (with a degree in agriculture, or equivalent, and preferably with some tropical experience) in Agriculture at the Imperial College of Tropical Agriculture, University College of The West Indies, Trinidad—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1.

Lecturer (with an honours degree or equivalent qualification in metallurgy or physics) in the School of Metallurgy, University of New South Wales, Australia—The Agent-General for New South Wales, 56–57 Strand, London, W.C.2, and The Appointments Section, University of New South Wales, Box 1, Post Office, Kensington, N.S.W., Australia.

Master (with a good honours degree) to teach Chemistry throughout the School—The Headmaster, King Edward VII School, Lytham.

Physicists, to carry out independent research and to take an interest in a broad range of applications of physics to the building industry—Dr. A. R. Collins, Director of Research and Technical Services, Cement and Concrete Association, Wexham Springs, Stoke Poges, Buckinghamshire.

Postdoctoral Research Fellow in Organic Chemistry—Prof. R. C. Cookson, The University, Southampton.

Postgraduate Research Assistant (with a knowledge of X-ray diffraction methods), for studies of liquid structure under the personal supervision of Prof. J. D. Bernal—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1.

Research Assistant (preferably with experience in cytology), to take part in a programme designed to study human chromosome abnormalities and associated disorders—The Secretary, Genetics Department, The University, Sheffield, 10.

Research Assistant, to help with current research on an immunological project connected with rheumatoid arthritis—The Pathologist, Stoke Mandeville Hospital, Aylesbury, Bucks.

Research Officer (Economic Botanist) (male, between 24–45, with an honours degree in natural science, two years postgraduate training, a good general knowledge of the subject, and preferably some field experience) in the Department of Agriculture, North Borneo, to deal with the selection and breeding of the major crops of North Borneo—The Director of Recruitment, Colonial Office, London, S.W.1, quoting Ref. BCD.63/21/09/C1.

Research Technician (with a knowledge of chemistry, physics or biochemistry) to assist in the study of biochemical changes to patients and experimental animals undergoing heart operations by means of heart-lung bypass procedures—The House Governor, Brompton Hospital, South Kensington, London, S.W.7, quoting PR2.

Senior Lecturer (qualified to teach microbiology to final degree and Diploma in Technology standard) in Microbiology—The Registrar (Department F), Bradford Institute of Technology, Bradford 7.

Senior Technician (Grade 1) or Scientific Officer for the Microbiological Assay Unit (Vitamin B_{12} and folic acid), City

General Hospital—The Group Secretary, Sheffield No. 1 Hospital Management Committee, "Lyndhurst", Nether Edge Hospital, Sheffield 11.

SENIOR TECHNICIAN I IN THE DEPARTMENT OF PATHOLOGY, for duties confined to experimental pathology—The House Governor, St. Mary's Hospital, Paddington, London, W.2.

APPOINTMENTS VACANT

AUSTRALIA
UNIVERSITY OF NEW SOUTH WALES
LECTURER
SCHOOL OF METALLURGY

The University of New South Wales wishes to appoint a Lecturer to the staff of the School of Metallurgy. The successful applicant will work in the fields of physical metallurgy or metal physics, and should preferably have had formal training and postgraduate experience in the physics of the solid state. Applicants for this position should have an honours degree or equivalent qualifications in metallurgy or physics. Salary: £A.1,772 range £A.2,477 per annum. Commencing salary is determined by qualifications and experience. After passing a medical examination, the successful applicant will be eligible to join the State superannuation scheme. He will be eligible, after six years of service for twelve months study leave on full salary. The University will pay travel expenses for the appointee and his dependent family and will meet reasonable removal expenses for furniture and effects. With the approval of the University and its bankers, married men may be assisted by loans to purchase a home. Inquiries about the School of Metallurgy may be addressed to the Head of the School, Professor R. H. Myers.

Four copies of applications, including the names of two referees, should be lodged with the Agent-General for New South Wales, 56-57 Strand, London, W.C.2, and a copy forwarded by airmail to the Appointments Section, Box 1, Post Office, Kensington, N.S.W.

BRITISH DRUG HOUSES LTD.

have a vacancy for a

YOUNG HONOURS GRADUATE

to work in their RESEARCH DEPARTMENT in the STEROID FIELD.

The Company offers good conditions of employment.

Write, with full details of age, qualifications, and salary required, to:

Ref. HAC/VP, Personnel Manager,
The British Drug Houses Ltd.,
Graham Street, London, N.1.

TORRY RESEARCH STATION
D.S.I.R.

requires Scientific Officer for Humber Laboratory, Kingston-upon-Hull, Yorkshire, to work on problems of both fundamental and applied research concerned with fish-smoking; the transport of fresh and frozen fish; and the manufacture of fish meal. Qualifications: first- or second-class honours degrees in chemical engineering or in chemistry, with postgraduate training or experience in chemistry. Salary: £738 to £1,222.

Application forms from Director, Torry Research Station, Aberdeen, quoting TORRY 8Z.

ROAD RESEARCH LABORATORY (D.S.I.R.), Harmondsworth, Middlesex, requires Civil Engineers, Physicists, Mathematicians, Statisticians in the Senior Scientific and Scientific Officer grades for work in the Tropical Section. Duties concern problems of road building and road transport in tropical and sub-tropical areas, involving soil mechanics, traffic engineering, and economics studies. Section is based at Harmondsworth and work involves regular visits overseas with, in some instances, postings for periods of one or two years on specific projects: usual Foreign Service Allowances apply. Qualifications: First- or second-class honours degree. For Senior Scientific Officer some years of appropriate postgraduate research is required. Salary, within range: Scientific Officer, £773 to £1,267; Senior Scientific Officer, £1,392 to £1,714. Prospects of promotion to Principal Scientific Officer (range up to £2,478) with possibility of higher posts. Laboratory is expected to move to Crowthorne, near Bracknell, Berkshire in 1963-64.—Application form and further information from Director of Road Research (address above), quoting ROAD8YXW.

IMPERIAL CHEMICAL INDUSTRIES LIMITED

Fibres Division

The Fibres Division of Imperial Chemical Industries Limited invite applications from

SCIENCE GRADUATES

preferably women

with qualifications or experience in the fields of CHEMISTRY or TEXTILE TECHNOLOGY, to work as an

ABSTRACTOR

in their Technical Library

Conditions of employment include a five-day week, membership of staff pension fund, an employees profit-sharing scheme and canteen facilities.

Written applications, giving brief personal particulars, to:

Division Staff Officer,
Personnel Department,
IMPERIAL CHEMICAL INDUSTRIES LIMITED,
Fibres Division,
Hookstone Road, Harrogate, Yorkshire,

quoting Ref. T.40/C.

PHYSICAL RESEARCH CHEMIST

Applications are invited from physical chemists, preferably with several years' postgraduate experience, for a post concerned with fundamental studies on gelation at the British Gelatine and Glue Research Association, 2a Dalmeny Avenue, London, N.7.

The post carries F.S.S.U. benefits and other conditions usual in Research Associations.

Applications should be made to the Director of Research by August 14, 1961.

UNIVERSITY OF CANTERBURY
CHRISTCHURCH, NEW ZEALAND
LECTURER IN BOTANY

Applications are invited for the above-mentioned position. Applicants should be honours graduates in botany or microbiology of some British Commonwealth or foreign university and have had some previous experience of university teaching. They should also be qualified to lecture on fungi and bacteria to botany students, including postgraduate students, and to give a course on applied microbiology. Preference will be given to candidates with experience in microbiology. The salary will be £1,250 per annum, rising to £1,700 per annum. Approved fares to Christchurch will be allowed for the appointee, his wife and children; in addition, actual removal expenses will be allowed within specified limits.

Further particulars and information as to the method of application, may be obtained from the Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1. Applications close, in New Zealand and London, on August 15, 1961.

AGRICULTURAL RESEARCH COUNCIL
ANIMAL BREEDING RESEARCH ORGANIZATION

Animal Physiologist with research experience required to develop work in the field of adaption of animals to environment. Good laborator facilities including controlled climate chamber are available at Roslin, 7 miles from Edinburgh. These facilities have been designed primarily, bu not exclusively, for sheep. Salary according to qualifications and experience. Scientific Officer £800 to £1,222; Senior Scientific Officer, £1,342 to £1,654; Principal Scientific Officer, £1,716 to £2,418. Superannuation in F.S.S.U.

Apply not later than July 29, to the Secretary Animal Breeding Research Organization, Glenbourne, South Oswald Road, Edinburgh, 9, from whom further information may be obtained.

DEPARTMENT OF SCIENTIFIC AND INdustrial Research: Textile Technologist. Pensionable post, graded Principal Scientific Officer at Tropical Products Institute, London, W.C. for man or woman to supervise group concerned with research into, and laboratory examination of various aspects of animal and vegetable fibre pulp, paper and board-making materials, hides skins, etc., of tropical origin. Qualifications: normally first- or second-class honours degree in textile technology, chemistry, or physics, or Associateship or Fellowship of Textile Institute (or equivalent). Candidates without the prescribed qualifications may be considered if they have experience in the science or technology of one or more of the above commodities, and ability to supervise scientific and technical staff essential Interim salary scale (Inner London), £1,781 to £2,483. Starting salary may be above minimum Promotion prospects.—Write Civil Service Commission, 17 North Audley Street, London, W.1, for application form, quoting **S/5333/61**. Closing date August 15, 1961.

SCIENCE FOR SCIENTISTS AND TECHNOLOGISTS

PRE-OCCUPIED as they are with problems of providing sufficient quantities of concrete and glass to accommodate all the pressing applicants, university leaders have found it difficult of late to spare the time to consider the kind of teaching which will best serve the graduate scientist or technologist. In his statement to Convocation of the University of Leeds, the vice-chancellor, Sir Charles Morris, wisely resisted the temptation to deal with the expansion difficulties of the 'sixties and concentrated on the problems which are immediately in front of all university teachers and administrators and which all can help to solve.

Chief among these is the kind of science which should be included in undergraduate courses for scientists and technologists. Despite the accelerating pace of scientific discovery, the problem of adjusting syllabuses to meet the needs of students of pure science are, though difficult, not insuperable. Although much that was considered essential in the past necessarily has to be cut out, at regular intervals there is a rethinking of the principles on which courses and syllabuses have to be rebuilt, and this is done at not infrequent intervals.

With the applied sciences however, and this applies to medical as well as technological courses, the situation is quite different. Here knowledge of a pure science is not an end in itself. It is a piece of equipment which is necessary before the study of the applied science or the acquirement of professional skills can be initiated. The underlying danger is that the amount of knowledge of the pure sciences which teachers of technology demand may be much more than individual students can humanly be expected to absorb.

Nor are the difficulties confined to the students. Studies undertaken by pure scientists in teaching the applied scientists are becoming so exacting that the prospect of the pure science departments themselves becoming considerably changed in nature and direction is by no means remote. The prospective engineer or metallurgist or medical man regards his basic chemistry, physics and mathematics as so many obstacles to be got over before embarking on the studies that matter. Teaching physics or chemistry to such students involves much routine work and, to sustain student interest, demands not only much pedagogical skill but also a considerable quantity of evangelical zeal. To maintain continual interest, the teacher may have to resort to methods of teaching which may not always have been thought appropriate in university departments.

This is a problem which needs speedy resolution if departments of pure science are to continue to flourish both as centres of creative investigation and places where pure scientists themselves may be taught. Sir Charles Morris believes that if this problem is not solved, "the departments of pure science as centres for the advancement of knowledge and homes for education of the pure scientists of the future, may in many universities wither and die". The alternative is that our future doctors and technologists may be brought up with insufficient knowledge of the basic sciences on which the whole structure of medicine and technology rests.

To push this problem back to the schools would provide no lasting solution. Already the fear exists that, so far as science is concerned, too much is being demanded of the schools. Since the amount of pure science required by the technologists will grow more rather than less, it would seem inevitable that the universities will be required to teach more pure science to the applied scientists.

The content of courses for technologists was also examined by Sir John Cockcroft, Master of Churchill College, Cambridge, in his Trueman Wood Lecture delivered to the Royal Society of Arts on April 26. Since their training should enable them to deal with the technological developments of the future rather than the problems of the past, Sir John suggested that university courses in technology should have a strong component of basic science. All students of technology, for example, should become familiar with the fundamentals of electricity and magnetism so that they can design equipment from first principles rather than handbooks. They should also know the principles of heat and thermodynamics, fluid dynamics as well as solid-state physics, which form the basis for understanding those solid-state electronic devices which are changing the face of technology. All basic training should stem from a good working knowledge of mathematics, particularly calculus and differential equations. Sir John would find wide support for his contention that mathematics should take priority over all other subjects in the training of sixth-form scientists who wish to enter a university or go directly into industry. Many would also support his view that to-day there is too much of a divorce between mathematics and physics in some universities, but would hesitate in replacing mathematics entirely by theoretical physics in the training of technologists.

In the first one or two years of university education, potential technologists should study physics, chemistry and mathematics, and Sir John commends as a model the Cambridge Natural Sciences Tripos Part I in which three or more sciences, including mathematics, are studied.

The training of engineers should follow the same general principles that apply to the training of other technologists. In his first two years, the engineer should study those principles of engineering science which underlie his technology. Only then should he begin to specialize and spend a large part of his time on electronics, thermodynamics, power engineering or other specialist subjects. Support for Sir John's thesis came recently from the Institution of Chemical Engineers, which recommended that about 45 per cent of the teaching in a university should be devoted to pure science and mathematics. About an equal amount of time should be devoted to chemical engineering science and the remainder to other engineering science, report-writing and a foreign language.

Regard for the way basic science is being taught in Australian universities has been expressed by Prof. A. E. Alexander, professor of physical chemistry in the University of Sydney (*Vestes*, **3**, No. 4; December 1960). Prof. Alexander's reflexions were mainly concerned with chemistry and stem largely from the low staff–student ratio. At the University of Sydney enrolments for chemistry in 1960 were 2,250 and were accommodated in eight parallel lecture courses, these being taken by three lecturers, two temporary lecturers, and three teaching Fellows. In Australia little sixth-form chemistry is taught in the schools and Prof. Alexander sighs for the British system so that the university could be spared an intolerable burden of mass production and be able to spend more time on teaching chemistry more appropriate to a university (see also *Nature*, 189, 444, 1961). For some time, however, the problem of large student numbers has to be faced and raises anew the questions posed by Sir Charles Morris—what kinds of basic science should be taught to applied scientists, how much of it should be taught in the schools and the university, and what teaching techniques the universities should adopt to deal with the inevitable large numbers. American universities have paid much more attention to what should be taught and how it should be taught, and both Britain and Australia have much to learn from them.

The time has surely come when such fundamental decisions should no longer be left to heads of departments or *ad hoc* committees composed of members whose main interests are in research. Should not each faculty of pure and applied science initiate major research projects, carried out by senior research Fellows, to determine the content of their courses, the way it should be taught, where the teaching should be done, how much should be left to the schools, how often revision should be carried out, and who should be consulted before revision takes place?

GOALS FOR SCIENCE IN THE UNITED STATES

IN February 1960, General (formerly President) Eisenhower announced the appointment of a Commission on National Goals, and requested the members of this Commission to "develop a broad outline of co-ordinated national policies and programs" and to "set up a series of goals in various areas of national activity". The Commission's report, including sixteen essays written by selected individuals, was prepared and published in a volume entitled *Goals for Americans*.

For its essay on science, the Commission chose Dr. Warren Weaver, vice-president of the Alfred P. Sloan Foundation, who, aided by the advice and counsel of a number of distinguished American scientists, presented his contribution, which he called "A Great Age for Science".

As this article was written by one of America's leading scientists, and because of the number of requests for the material, it has been reprinted separately by the Foundation for special distribution*.

Of primary importance in Dr. Weaver's thesis is the need to recognize the importance of science teaching, and to reward teachers at all levels of the educational system. The fact that this need has been appreciated for some time, and is fairly self-evident, does not detract from its intrinsic importance. Concern is growing in the United States about the present-day neglect and disparagement of teachers, which, long-existent at the more elementary levels, has now obtained a foothold in the universities. The university tradition of great scholar-teachers, dedicated to research, but eager and willing to teach younger students, is being undermined. Nowadays, scientists are being offered research posts with the added 'advantage' of very little teaching duty, and many full-time research scientists, working at the universities and receiving salaries from research contracts and grants, are, in the words of Dr. Weaver, "intellectual eunuchs, not at all involved in the propagation of their kind". Furthermore, the premium placed on particular types of scientists for certain industries (notably the defence industry) often leads to emergent Ph.D.s being offered research posts with salaries exceeding those of the professors supervising the theses. These trends are tending to denigrate the academic dignity and fundamental importance of teaching, and the trend should be reversed. It is Dr. Weaver's contention that there are no secondary roles so far as teaching and research are concerned; they should be equal partners.

Much space is devoted to a discussion of the position of science within the framework of society. That an enormous gap has opened up between the thinking of scientists and the views and attitudes of mind of creative artists and moralists is serious enough, but even more disastrous is the chasm which separates the scientist from the layman. Dr. Weaver quotes from *The New Yorker* of March 5, 1960: "These are hard times for the layman. He is no longer thought competent to work out his own opinions on many matters, even many that touch him intimately. His very survival has become the property of committees and the subject of learned arguments among specialists. He has little to say . . . being largely ignorant of the information upon which plans for him are based".

---

* *A Great Age for Science.* By Warren Weaver. Pp. viii + 35. (Reprinted from *Goals for Americans.*) (New York: Alfred P. Sloan Foundation, 1961.)

Science is involved in many present-day social and political problems, and, in a democracy, these problems should be the concern of the citizens as well as the scientists. Further to this, science in the United States is now largely financed by Government agencies, which are under the ultimate control of the citizens. People ought not to have to subscribe to something they know nothing about.

These points make it imperative that individual citizens should have an improved understanding of what science is, and how it operates.

On more specific but nevertheless highly important goals, the question of financial support for science is discussed. Often there is not enough distinction made between research and development, and a cursory glance at budget statements of 'R and D' (Research and Development) may give a misleading impression of the amount of support given to 'R'. The figures indicate an enormous increase in the support of development, but the financial aid given to basic research has not kept pace. Although American defence commitments require enormous sums to be spent on development of missiles, rockets, etc., there is some criticism of the fundamental philosophy of State policy in this direction; military interservice rivalry and lack of understanding of military objectives lead to wasteful duplication of developmental projects, and 'crash programmes', undertaken more as a result of emotion than of reason ('space' is the perfect example), lead to a budget which is heavily overburdened on the developmental side. It is argued that, with the introduction of a little more common sense, the total annual national allotment for pure research, which at the moment is in the region of 8–900 million dollars, could easily and profitably be raised to 1,500 million dollars without increasing the overall research and development figures.

Attention is also directed to the part played by industry in promoting basic scientific research. Although most of the misguided, old-fashioned acrimony between academic and industrial scientists has now disappeared, only a very few of the best American industries have established a satisfactory liaison between the interests of the community and the interests of the individual. Other industries, although giving the appearance of following this pattern, do not, in fact, go far enough. Furthermore, although there has been great improvement, industries do not, in general, give enough support to research and education in universities and colleges, or to development of particular fields of science on which they themselves depend.

'Crash programmes', which work on the false assumption that 2 billion dollars equal one solved cancer problem, often lack adequately trained and able personnel, and, most important of all, there has not been established a basic theory to work on. What is needed is a broad attack at the roots of a problem by means of reasoned, fundamental research rather than a phrenetically active but superficial attack, which reflects adversely on national maturity and prompts Dr. Weaver to ask himself, "What's the rush ?"

ROTATION OF THE EARTH

The Rotation of the Earth

A Geophysical Discussion. By Walter H. Munk and Gordon J. F. Macdonald. (Cambridge Monographs on Mechanics and Applied Mathematics.) Pp. xix + 323. (Cambridge: At the University Press, 1960.) 70*s*. net.

THIS masterly book very well conveys the intellectual excitement of present-day geophysical research. From an examination of the places from which ancient eclipses were observed, Halley pointed out that the Moon's motion in longitude was gradually accelerating. Some of the best mathematical minds in the eighteenth century concerned themselves with the complex problem of providing a complete theory of the motions of bodies of the solar system, and Laplace in 1787 finally decided that this acceleration of the Moon was due to a decrease in the eccentricity of the Earth's orbit arising from gravitational perturbations by the planets. However, about the middle of last century, J. C. Adams showed that Laplace had neglected certain terms and that, in fact, only half the acceleration of the Moon could be explained by purely gravitational causes.

Gradually it became evident that the discrepancy was due to a secular increase in the length of the day, that is, a slowing up of the Earth's rotation. The much more detailed knowledge of the Moon's longitude, acquired through astronomical measurements in the past few hundred years, has shown that in addition to this secular acceleration of the Moon's longitude there are irregular changes with a time scale similar to that of the geomagnetic secular variation (about 50 years). The work of numerous astronomers, culminating in the famous paper of Spencer Jones in 1939, showed that these irregular fluctuations are also due to the changes in the length of the day. Since the War the Earth's rotation has been timed accurately over much shorter periods still by quartz clocks and an annual term in the Earth's rotation discovered.

About a hundred years ago astronomical determinations of the latitude of observatories became accurate enough to detect that the Earth's axis of rotation is wobbling, with respect to the Earth, a few tens of feet during periods of twelve months and fourteen months. The extraordinary accuracy of astronomical measurements by which these various phenomena have been discovered should be a cause of wonder: the irregular changes in the length of the day, for example, are about one part in 10^8. All these phenomena give very important information about the Earth, and Munk and Macdonald give a fascinating description of the analysis required to explain them. The secular deceleration of the Earth appears to result from the friction of the lunar oceanic tides; the irregular fluctuations in the length of the day from the turbulent motion in the Earth's core, which produces the magnetic field; and the seasonal changes from asymmetry in the atmospheric circulation in the southern and northern hemispheres. The exciting forces which cause the Earth to wobble on its axis are unknown, and this causes some difficulty at present in making reliable inferences concerning the properties of the interior of the Earth from the variation of latitude data.

However, on the whole, all the observations of phenomena so far referred to can be explained without having to assume any very startling new departures in geophysical thinking, and so, as Munk and Macdonald show, a mathematically satisfying and fairly tidy story results. However, for the completeness of their account of the idiosyncrasies of the Earth's rotation, Munk and Macdonald refer to the evidence, which has accumulated in recent years from palæomagnetic work, that large changes of the relative positions of the axis of rotation and the continents have occurred gradually over hundreds of millions of years. These theories of 'polar wandering' and 'continental drift' were vigorously debated thirty years ago by geologists and geophysicists and were then largely discredited. Munk and Macdonald discuss the possibility of producing large polar wandering, but they baulk at the idea of continental drift. Instead, they take refuge in a somewhat unsympathetic discussion of the palæomagnetic evidence, although these data are massive in quantity and are probably more statistically significant than some of the other observational evidence which they accept quite happily in the earlier part of their book. The beauty of the book is to show how evidence from such widely different fields as geology and positional astronomy must be woven together to understand this central problem of geophysics.

S. K. Runcorn

ASTRONOMY IN THE MAKING

The Controversy on the Comets of 1618

By Galileo Galilei, Horatio Grassi, Mario Guiducci and Johann Kepler. Translated by Stillman Drake and C. D. O'Malley. Pp. xxv + 380. (Philadelphia: University of Pennsylvania Press; London: Oxford University Press, 1960.) 48*s*. net.

As the links of the new astronomy were being forged in the seventeenth century, controversies, often heated and sometimes polemical, arose among the *cognoscenti*. On one hand the Aristotelian and Ptolemaic universe was upheld, having the respectability of authority and the blessings of the Church behind it; on the other the revolutionary ideas of Copernicus and Tycho Brahe were advocated by Galileo and Kepler, who also had their own novel contributions to make and who were supported by others of like mind. One of the difficulties of looking back on these formative years is so to stimulate the imagination that one can obtain something of the essence of the reality of the problems which had to be solved. It is only too easy to judge with a decision based on what we now know was later to be discovered and proved. Probably the best way out of this difficulty is, where possible, to read the actual arguments which took place and, moreover, to read them in the words of the actual protagonists concerned.

In the autumn of 1618 there appeared three bright comets, visible to the naked eye. The question arose whether these objects were meteorological in nature or whether they were truly celestial bodies and, if the latter, what really was the nature of their paths. The appearance of the comets aroused wide interest, many pamphlets about them appeared, and Galileo, then aged fifty-four, entered the arena of controversy and produced his brilliant polemic *Il Saggiatore*. This book is important not so much for its scientific content or its literary merit, high though this is, but primarily for an insight into Galileo's approach to scientific matters; modern scientific method is here seen as it was in its early stages.

Yet Mr. Drake and Dr. O'Malley have, in their book, done more than provide, for the first time, a translation of the whole of *Il Saggiatore*, for they have also placed this gem in its appropriate setting. This they have achieved by beginning with a translation of Gassi's disputation on the three comets and giving also his *Libra Astronomica*, which was published under the pseudonym of Lothario Sarsi. Interspersing Gassi's work is a translation of Guiducci's discourse on the comets (and really written by Galileo), and following Gassi's *Libra Astronomica* there is Guiducci's own letter about the matter written to his old professor, Tarquinio Galluzzi. *Il Saggiatore* comes next, and then there are appended Kepler's remarks on it taken from his *Tychonis Brahei Dani Hyperaspistes*. Thus, within the covers of one volume, we have the whole of the controversy over the three comets.

The works given are, of course, eminently readable, for their authors wrote well and the translations which have been made are excellent. Excellent also is Mr. Drake's nineteen-page introduction in which he sets out very clearly sufficient of the ramifications which lay behind the controversy and of the nature of the protagonists to make the translations illustrate their points clearly. Throughout the book there are references to notes which, given at the end of the volume, elucidate various points or obscurities in the main body of the text, and there is also an adequate index. Well printed in England, the price of the book may seem, perhaps, rather high, but nevertheless this excellent contribution to the history of science is much to be recommended.

Colin A. Ronan

THEORETICAL METEOROLOGY

Introduction to Theoretical Meteorology

By Prof. Seymour L. Hess. Pp. xiv + 362. (New York: Henry Holt and Company; London: Constable and Co., Ltd., 1959.) 60*s*. net.

This is an important new text-book written primarily for students, but equally suitable for those desiring an up-to-date review of the subject. The aim has been to provide a reasonably rigorous treatment which is not rendered unnecessarily difficult by advanced mathematical arguments. The first seven chapters are devoted to basic thermodynamics, the properties of water vapour and hydrostatic stability, and the next three chapters to radiation theory and its application to the Earth-atmosphere system. The remaining eleven chapters deal with dynamics, including viscosity, turbulence and modern numerical techniques.

The main emphasis is placed on large-scale properties of the atmosphere. The general circulation and the role of depressions and anticyclones in its maintenance receives a thorough treatment which brings the reader with a minimum of difficulty right to the frontiers of our knowledge of what is probably the most fascinating of all meteorological problems. On the other hand, smaller-scale phenomena such as sea-breezes are given a somewhat cursory treatment, and mountain waves are not mentioned at all, even though they have received much attention in recent years. Convection is discussed in more detail, but the impression given that a convection current behaves dynamically like a rising balloon subjected to viscous drag is misleading, since an isolated convection element is now known to be a rising vortex ring. The author's derivation of the equations of motion of the atmosphere is somewhat novel and will appeal to many, but may not satisfy those who are mathematically inclined. A more rigorous derivation, preferably using vectors, could well be appended.

These criticisms of detail must not be allowed to detract from the overall good quality of this book. The author's style is lucid and his presentation of some concepts, such as inertial stability and the vorticity equation, is particularly attractive. The examples at the end of each chapter are well designed and will help the student to acquire a knowledge of the factors which are of primary importance in the many and varied physical problems encountered in meteorology.

ROBERT P. PEARCE

INCOMPRESSIBLE AERODYNAMICS

Incompressible Aerodynamics

An Account of the Theory and Observation of the Steady Flow of Incompressible Fluid past Aerofoils, Wings, and other Bodies. Edited by Bryan Thwaites. (Fluid Motion Memoirs.) Pp. xx + 636. (Oxford: Clarendon Press; London: Oxford University Press, 1960.) 75*s*. net.

THIS book is the first of a new series of Memoirs on Fluid Motion which will also include volumes on laminar boundary layers and turbulence. It addresses itself to a class of problems which have been pushed off the centre of the aerodynamics stage by the current fashion for magnetogasdynamics, hypersonics, rarefied flows and all the other exotic fields associated with space flight or long-range rocketry—namely, the many non-linear problems of incompressible aerodynamics.

Nevertheless, these more old-fashioned problems of low-speed flight are neither irrelevant nor by any means solved or even fully understood, and the present volume is a welcome addition to the library of those in the aeronautical profession who are still concerned with aircraft which must take off, manœuvre and land with a reasonable degree of effectiveness and reliability; nor will it be found trivial by those many lovers of fluid mechanics who are fascinated by rotational and separated flow-patterns.

The basic thread which runs through this book is the subtle interplay of models of flow patterns suggested by ingenious experiments (both detailed measurements of pressures and visualization of flow fields by means of smoke, tufts and other devices) and approximate analytical techniques designed to fit the observed flow patterns into the fabric of classical aerodynamics. Never is the model over-simplified to make it amenable to analysis; never is mathematics pursued for its own sake to a sophistication beyond that of the physical picture. At all times, the relevance of the questions and of the answers to the design of more effective machines is clearly kept in mind.

Among the sections which I have found of particular interest, those which deal with stalling wings, separated flows over swept wings and thick wakes, appear outstanding; but this judgment is most likely a reflexion of my tastes. The treatment of almost all the difficult low-speed flight problems by ingenious methods is fascinating and a worthy monument to the men, largely at the National Physical Laboratory and the Royal Aircraft Establishment, who created a distinctive English style in aerodynamics, compounded of sound technique, balanced judgment and a profound intuitive feeling for the physics of fluid flow problems.

LEON TRILLING

INFRA-RED ARTS

Infrared Methods

Principles and Applications. By G. K. T. Conn and D. G. Avery. (Physical Chemistry: a Series of Monographs, Vol. 7.) Pp. viii + 203. (New York: Academic Press, Inc.; London: Academic Press Inc. (London), Ltd., 1960.) 6.80 dollars

A SPECTACULAR change in the attitude of chemists over the past twenty years has been their acceptance of physical methods for solving problems, particularly in organic structural work and in analysis. Among these methods is infra-red spectroscopy, which is now, and is likely to remain, a routine tool of the chemist. The arrival of 'simplified' commercial instruments is making the infra-red spectrometer as commonplace in laboratories as the refractometer and is creating a class of user who has no interest in spectroscopy for its own sake and little in the principles of operation and design of instruments; infra-red spectroscopy is no longer the preserve of the physicist and physical chemist. Any book with the broad title *Infrared Methods—Principles and Applications* is thus likely to have drawn to it the attention of a very large number of students and research workers. It must be said, however, that many of these will find the title misleading, for the principles are those involved in generating, dispersing, and detecting infra-red radiation, the applications are in the calibration of detectors, the production of monochromatic radiation, in the design of instruments for industrial gas analysis and plant control, and in pyrometry. This book is written from the point of view of the experimental physicist, and when the authors suggest that it is an introduction to infra-red studies for "the research student and the student in allied fields" it should be understood that they refer to the research student of spectroscopy or allied fields of physics. The average worker in other fields who wants to understand how an infra-red spectrometer works and what its limitations are will find it far beyond his needs. Authors write as they view the subject, but it does seem remarkable to find a work such as this in a series of monographs on physical chemistry. There is, without doubt, a demand for an up-to-date authoritative account of practical methods in infra-red spectroscopy written with chemical applications strongly in mind. This monograph does not satisfy it.

The chosen material is presented in a clear manner with a fair number of references to original papers. The book is beautifully produced, only two errors being noted, in figures I. 2 and V. 5.

E. S. WAIGHT

THE ELECTRON MICROSCOPE

The Electron Microscope

The Present State of the Art. By M. E. Haine, with a Chapter on Applications in Collaboration with Dr. V. E. Cosslett. Pp. xvi+282. (London: E. and F. N. Spon, Ltd., 1961). 55*s*. net.

THIS book, by the best British electron microscope engineer, with a chapter on applications written in collaboration with the doyen of British experts, is in many ways the last word on the electron microscope. It took the optical microscope 200 years to develop, from Leeuwenhoek to Abbe, from the 'dewdrop' to the apochromat. The electron microscope took less than 25 years from the primitive 'magnifying glass' of Knoll and Ruska, to the attainment of the present limiting resolution of about 6 Å., also by Ruska, in 1954, which, as readers of this book will soon become aware, is not likely to be much bettered in the future.

In the optical microscope two centuries of work went into correcting the aberrations, and the work is not yet quite finished. In electron optics it took only a few years before Scherzer demonstrated that the spherical aberration could not be corrected, and the question was only to find the optimum. In the electron microscope all the essential 'optical design' now boils down to a single curve (Fig. 1,7, p. 8), computed by the late G. Liebmann, one of the principal author's able collaborators, from which designers can pick their choice, according to the number of ampere turns which they are willing to embody in their objectives. The optimum theoretical resolution is about 2·7 Å. at 50 kV. and could be reduced to 1·5 Å. at 400 kV.—probably at the expense of contrast. The reasons why the practical resolution is only about one-half of the theoretical are fully and ably explained by Dr. Haine. It is particularly welcome that, apart from a detailed discussion of astigmatism, vibrations, creep, contaminations, etc., he describes, in full practical detail, the remarkable Haine-Mulvey Fresnel fringe test, so that every user of an electron microscope can test for himself the resolution limit of his own instrument.

The resolving power of the electron microscope has stopped at a particularly uninteresting stage. There are very few objects of 6 Å. size; organic molecules of this size have insufficient contrast, metal colloids tend to grow spontaneously to about twice this size, atomic lattice spacings are finer. (Only J. W. Menter was able to find an interesting example, by directly resolving the lattice of molybdenum trioxide, Fig. 10. 25, p. 270). If the resolution limit could be reduced below 3 Å., most atomic lattices could be resolved. The present book makes it clear why attempts to achieve this have failed, and are probably bound to fail for a long time—such as Scherzer's remarkable non-rotational lens, and the reviewer's suggestion of taking an imperfect electronic image, which is complete as it contains a record of phases as well as of amplitudes, and doing the corrections with light, in a second, optical process. The difficulties are so formidable that for a long time the electron microscope is bound to stay at the present limit—which, however, does not exclude interesting new special types, such as high-voltage instruments and interference microscopes, and the standard instrument will become a more and more convenient instrument for the user.

It is to the user—the biologist, the metallographer, the physical chemist—that this book is chiefly addressed. Correspondingly the mathematics is cut down to a minimum, but the critical attitude of Dr. Haine, who cannot suffer obscurities, has forced him to make this minimum so complete that it is somewhat doubtful whether most of the users of electron microscopes will not find it far above their heads. It takes a specialist to appreciate fully the amount of critical thinking which has gone into this book. I believe that it will have its greatest effect in the case of that small but important and growing class of users who are fully trained physicists (working mostly on imperfect crystals, such as metals) and who are willing to go to some pains to understand not only their object but also their instrument.

D. GABOR

ORGANO-METAL COMPOUNDS

Organo-Metallic Compounds

By Prof. G. E. Coates. Second edition. Pp. xiii+366. (London: Methuen and Co., Ltd.; New York: John Wiley and Sons, Inc., 1960.) 45*s*. net.

THE original stimulus for the investigation of organo-metallic compounds came from the possibility of their use in organic synthesis. Indeed, many chemists a decade or so ago were really familiar with only one class of compounds, namely, the Grignard reagents. To-day there exists an extensive subject covering compounds of almost all the known elements, which is rapidly developing and which is followed by many different kinds of chemist. The impressive advances which have been made have in many cases been the product of co-operation between theoretical, organic, inorganic and physical chemists. Synthetic organic chemistry is still, however, a major beneficiary from the investigation of these compounds, but there is an ever-increasing independence emerging in the studies in this field.

The first edition of this book (190 pages) appeared as a Methuen Monograph in 1956, having been written for the most part in 1953–54, with a section on the cyclopentadienyls having been added in proof. In the intervening years the amount of published work has been very great, so that even with certain condensations of material, notably that concerning organo-boron compounds, the second edition now comprises 360 pages and, in addition, has a larger page size. Such an expansion is inevitable and is completely justified in that this new and enlarged edition presents an almost complete picture of those compounds in which a direct metal–carbon bond is present. As in the previous edition the extensive organic chemistry of phosphorus, arsenic and silicon is omitted. The layout is little changed, but certain new theoretical and industrial aspects are now included. The main changes are to the sections on the alkali metals, boron, tin and the transition metals. This latter section has been expanded from 27 to 127 pages and now includes a thorough description of certain of the transition metal complexes in terms of molecular orbital theory. Throughout, complexes are discussed in terms of σ or π bonding.

The author's personal enthusiasm and experience in this field are clearly apparent, particularly in certain of the descriptions of preparations in which considerable detail is given; an aspect which should add considerably to the value of the book for those actually working in the field. Others will find the wide coverage of this book most helpful in obtaining an appreciation of the present position of organometallics. The book is marred unfortunately by a number of typographical errors. The first edition was cheap at 12*s*. 6*d*. The second edition is reasonably priced at 45*s*. in view of its increased coverage.

D. S. Payne

RADIATION CHEMISTRY OF ORGANIC COMPOUNDS

Radiation Chemistry of Organic Compounds

By Dr. A. J. Swallow. (International Series of Monographs on Radiation Effects in Materials, Vol. 2). Pp. xiii+380. (London and New York: Pergamon Press, 1960.) 84*s*. net.

In this book the author defines his objectives as the presentation of an overall picture of radiation chemistry and a review of the published work on the subject between 1895 and 1958. He begins with a brief introductory account of the interaction of radiation with matter, and a discussion of the transient species formed by radiation. The transient species are simple in the extreme compared with the highly complex systems to be discussed later in the book.

There follows a chapter on experimental methods which deals, only in outline, with radiation sources, purity of materials—a feature often overlooked, says the author, in some of the experimental work reported on—analysis of products, and dosimetry. In no sense is this a practical manual of techniques, but it surveys very adequately the background to the chapters which follow.

Very wisely, the author devotes the next chapter to the radiation chemistry of aqueous systems, partly because he can illustrate the fundamentals of the mechanism of radiation changes, and because of the importance of aqueous systems for the understanding of radiation effects on biological systems. The four chapters which follow deal with aliphatic and aromatic compounds, polymers and dyestuffs. In these chapters the author's task was difficult in the extreme for, as he says, mechanisms are not yet fully understood even for simple molecules. Thus, much of the material presented catalogues the results of radiation of a vast range of compounds, with comments on mechanism where this is even partially understood. I would have liked more comment on mechanism, no matter how speculative it had to be. The author deserves great credit for the thoroughness of his searches before presenting this—and the other material in the book.

The next chapter deals extensively with radiation effects on substances of biological interest, with limited reference to *in vivo* systems, and the final chapter deals with such diverse topics as the origin of organic compounds in the history of the Earth, radiotherapeutics, sterilization of pharmaceutical products, food, and detailed investigation of the economics of commercial radiation. This chapter contains the surprisingly few examples of commercially feasible radiation processes which have been discovered, in spite of the vast amount of irradiation experimentation in the laboratory. The importance of radiation damage to organic coolants and lubricants for reactors is also discussed.

Although it has a few stylistic defects, the book is written with great clarity, without unnecessary preamble or loquaciousness, in a refreshingly direct way. It covers an amazing range of material, which is referred to by a sensible reference system collected at the end of the book. The chapters are constructed according to well-established rules of learning—a brief statement of the aims of the chapter, the detailed discussion, then a brief statement of the results.

The main value of the book lies in the fact that it makes readily accessible the state of knowledge about particular systems. Its discussion of mechanism is necessarily brief; but since such a book as this in a subject which is rapidly growing will surely be revised, the author might consider greater elaboration of the discussion on fundamental aspects of the subject, whether the knowledge is speculative or tentative or otherwise, perhaps at the price of compressing some of the factual matter into tabular form. The present structure of the book reflects the way in which the subject has grown empirically, without a detailed and exact theoretical basis. Perhaps this situation will change in the cycle of experiment, theoretical interpretation, prediction, and further enlightened experimentation.

PHYSICAL METHODS OF ORGANIC CHEMISTRY

Physical Methods of Organic Chemistry

Part 3. Edited by Arnold Weissberger. Third, completely revised and augmented edition. (Technique of Organic Chemistry, Vol. 1, Part 3.) Pp. xii+1799–2634+13. 184*s*. Part 4. Edited by Arnold Weissberger. Third, completely revised and augmented edition. (Technique of Organic Chemistry, Vol. 1, Part 4). Pp. xii+2635–3539+65. 195*s*. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1960.)

The general features of *Physical Methods of Organic Chemistry* have been indicated by the present reviewer when commenting on Parts 1 and 2, which were issued a year ago (*Nature*, 189, 954, 1961). Parts 3 and 4, which have now appeared, keep to the same general type in that they are mainly written by physicists for chemists and do not explain sufficiently the scientific significance of the types of measurements which they describe. However, organic chemists to whom the volumes have, by title, been commended will find Parts 3 and 4 of much more interest than Parts 1 and 2, since these survey the major optical and electrical techniques in use to-day for the investigation of molecular structure.

Part 3 deals mainly with optical measurements. Two sections on "Spectroscopy and Spectrophotometry" from the old edition have now been expanded to five chapters without inclusion of superfluous material. The chapter on "Ultraviolet and Visible Spectroscopy" (150 pages) can be commended as a well-balanced review in which technical improvements are brought to notice and the structural significance of experimental results is explained in simple terms.

In contrast, the chapter on "Infrared Spectroscopy" deals almost exclusively with intrumentation and techniques, but this is to be excused since Volume 9 of the general series has dealt with the subject.

A number of following chapters on colorimetry, fluorescence, light scattering and polarimetry have few novel features, but, following these W. Klyne and A. C. Parker have written a new chapter on optical rotatory dispersion to deal with the major recent development of polarimetry which has had, in the past five years. a profound influence on knowledge of structural organic chemistry. Half this chapter is devoted to a judiciously selected survey of recent experimental data together with their cognate theoretical interpretations. The chapter can be commended as a concise, well-explained summary of this important subject.

Again, a new chapter by C. G. and R. J. W. le Fèvre on the Kerr effect is a useful addition to the treatise, but the same can scarcely be claimed of a later new chapter on the Faraday effect which, as yet, has found little practical or even theoretical applicability. Old, but slightly revised, chapters on determinations of dielectric constants and of dipole moments complete this volume.

Part 4 has several quite new chapters. Microwave spectroscopy is accorded 35 pages and, following this, nuclear magnetic resonance is surveyed by H. S. Gutowsky in a well-balanced 130-page chapter. The use of this important technique receives sufficient description for the chemist who wishes to be conversant with its applicability without having to delve too deeply into quantum theory. Following this the treatment of paramagnetic resonance, in 70 pages, is too heavily mathematical and fails to give an adequate impression of the value of this type of measurement. There is no indication that this type of measurement may be of particular value to biochemists in elucidating the behaviour of such complex substances as active preparations of enzymes.

After these chapters, that on the determination of magnetic susceptibility, by P. W. Selwood, is old and conventional. The author has discussed applicability in terms of organic chemistry but has failed to indicate the growing significance of this technique for inorganic chemists, although these scientists are more and more concerning themselves with organo-metallic compounds of diverse types.

Old chapters on conductometry, electrophoresis and polarography have been revised slightly and two new ones on determination of transport numbers and controlled-potential electrolysis have been added. The theoretical significance and the synthetic applicability of this last technique fully merit the attention which it has been accorded; these aspects of the subject receive adequate treatment. Determination of radioactivity has been accorded a hundred pages and is not over long, for there have been major developments of experimental techniques since the last edition of this book appeared. Very properly the chapter deals mainly with the counting of carbon-14 and of tritium, but describes, in full, the chemical procedures required for the conversion of organic substances into samples suitable for radioassay. Finally, the chapter on mass spectrometry, thoroughly modernized, closes the book. It again can be commended for devoting more than half its length to applications in both pure and applied organic chemistry. Due note has been taken of the conjoint use of mass spectrometry and gas chromatography.

The high cost of these volumes will undoubtedly restrict their sale, except to reference libraries, but, considering the excellence of the printing and the clarity of the diagrams, they could scarcely be produced more cheaply. However, since these two parts contain the chapters to which reference will most regularly be made, potential users should seriously consider the advisability of purchasing individual parts of the work rather than the complete set of four volumes.

W. A. WATERS

CHEMISTRY AND THE NERVOUS SYSTEM

The Neurochemistry of Nucleotides and Amino Acids

A Symposium of the Section on Neurochemistry, American Academy of Neurology. Edited by Roscoe O. Brady and Donald B. Tower. Pp. xii+292. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1960.) 80*s*. net.

Phosphorus Metabolism of Brain

By Dr. P. J. Heald. Pp. vii+195. (London and New York: Pergamon Press, 1960). 42*s*. net.

THE Neurochemistry of Nucleotides and Amino Acids, being a symposium of multiple authorship, exhibits considerable variety of style and approach among the thirteen main contributors. The articles on adenine nucleotides (by E. G. Trams), on guanine nucleotides (by D. R. Sanadi) and on the phosphatide bases (by D. M. Greenberg) range far beyond the confines of neurochemistry. Dr. Greenberg's paper was originally delivered *in absentia*, and in its printed form is accompanied by a running commentary in footnotes from Dr. J. Stekol, who actually read the paper for Dr. Greenberg at the meeting on which this book is based. This novel variant of the 'invited discussion' may, as the sessional chairman observed, become a precedent for a new kind of symposium. Other notable contributions more directly oriented towards the nervous system are those by R. J. Rossiter and his co-workers on the cytidine nucleotides and by N. O. Kaplan on the pyridine nucleotides. The section on amino-acids contains a thoughtful review by H. Waelsch, with A. Lajtha, on protein metabolism in brain, and two papers on γ-aminobutyric acid which, however, deal mainly with metabolic minutiæ. Some of the recorded discussion might have benefited from rather more drastic editing, but Dr. Tower has written a useful summary which effectively rounds off this lively series of mainly neurochemical snippets.

Dr. Heald's book on the *Phosphorus Metabolism of Brain* is a slim volume with a high density of contained information, and, for a biochemical monograph, it has the distinction of not including a single chemical formula of the classical type. The opening pages summarize data on the composition of normal brain in respect of phosphorus compounds, the text being fully documented and embellished with several compendious tables. Such compression of material reflects much labour in compilation, but imposes some initial strain on the reader, although for reference purposes it enhances the value of the section. In later parts of the book emphasis shifts towards the functional correlates of the reactions described and the writing gains in fluency. Research work based both on investigation of brains of whole animals and of isolated tissue preparations is considered, particular attention being given to the turnover of nucleotide and other 'high-energy' phosphates (where there is common ground between Dr. Heald and certain participants in the symposium reviewed above). The interpretation of experiments in which electric pulses are applied to slices of brain suspended in saline is judicially discussed, and a phosphoprotein which Dr. Heald has investigated figures in an intriguing, if speculative, scheme of reactions linking phosphate bond energy with ionic migrations in nerve cells. Other topics covered include the synthesis of phospholipids and the metabolic effects of anæsthetics; the book as a whole provides a comprehensive and timely survey of a field of study where general biochemical concepts such as that of energy-rich phosphate bonds may be related to the special features of a highly differentiated organ.

FLUORINE CHEMISTRY

Advances in Fluorine Chemistry

Vol. 1. Edited by Prof. M. Stacey, Prof. J. C. Tatlow and Dr. A. G. Sharp. Pp. vii+203. (London: Butterworths Scientific Publications, 1960.) 45*s*.

Chemie der Organischen Fluorverbindungen

Von Milos Hudlicky. Pp. xviii+416. (Berlin: Veb Deutscher Verlag der Wissenschaften, 1960.) 51.60 D.M.

ADVANCES in Fluorine Chemistry is an excellent beginning at fulfilling a critical need in the field of fluorine chemistry, namely, a systematic presentation and appraisal of the chemistry embodied in the various major areas of this rapidly expanding field. To cover all the areas with the attention that is their due is a monumental task. The editors of this book have selected a number of prominent British research chemists and teachers to write on five areas. These are: the halogen fluorides (W. K. R. Musgrave), transition metal fluorides and their complexes (A. G. Sharpe), fluoroboric acids and their derivatives (D. W. A. Sharp), the electrochemical process for the synthesis of fluoro-organic compounds (J. Burdon and J. C. Tatlow), and exhaustive fluorinations of organic compounds with high-valency metallic fluorides (M. Stacey and J. C. Tatlow). Each chapter is written with every attempt made not to be redundant. Whenever an earlier book or review article has made a contribution to the particular area under discussion it is cited as a prime source. As a result, in general, more emphasis is placed on the reactions and fundamental nature of the chemistry of both inorganic and organic fluorides than on the general preparative procedures, for the various authors are aware that a systematic fluorine chemistry is developing, is ready for more than a casual interpretation in terms of the science of chemistry and that the time has arrived to do so in earnest. Although there is a minor tendency, in some parts of the text, to extrapolate a bit beyond what may be construed as conservative, the facts are presented thoroughly enough to allow the reader to make his own interpretations, if he chooses to do so. At the same time, some of the writers of this book are courageous enough to be mildly critical of the authors they are citing when the occasion demands it. This is not a common practice, but appears with sufficient frequency to be stimulating.

This book is no less than its title advertises. It should prove helpful to the fluorine chemist in keeping abreast with the five areas discussed. If detailed data on a compended variety of fluorine compounds is what is being sought by the reader, he is referred to the more than adequate bibliography that follows each chapter. Typical of the better books by British authors, this book is up to date (1959), well written and discriminating. On the lighter side, the careful reader is in for a mild surprise when he reaches p. 11, and finds that gravity acts differently in England and in the United States.

In the introduction, Prof. Stacey states that this is the first volume in a series, and that further volumes written by chemists from several countries are to be anticipated.

The German edition of the book by Hudlicky is essentially a translation of the original edition in Czech reportedly brought more up to date by the addition of material that appeared in the chemical literature between the dates of publication. The author admits that the book is the result of his own attempts to enlighten himself in the area of fluorine chemistry.

The book meets rather well the purpose for which it was published, namely, to present in broad aspect the materials, conditions, yields and methods for preparing organic fluorine compounds. To this extent, the work is well done. No attempt is made to cover every appropriate compound produced or to compile the properties of those that are reported. Reaction equations, with conditions and yields, are used liberally to account for the results reported. Each such equation has a bibliographical reference and all information is cross-indexed by paper, author and compound, making it very simple to find any desired preparation. Consequently, even a student with a minimal comprehension of scientific German can use this book to good advantage.

There has been no attempt made to write this book for any purpose other than as a suitable reference text for information *apropos* laboratory practice in preparing organic fluorine compounds. There are a number of short chapters on nomenclature, materials for handling fluorine, reactions of fluorine with various substance, hydrogen fluoride and inorganic fluorides. To complete the book, sections on fluorine analysis, freons, and plastics containing fluorine are considered briefly.

The bulk of the text involves methods for putting fluorine into organic compounds, the various preparations of organic fluorine compounds, and their chemical reactions. A short chapter on the general physical properties of these compounds completes the book.

There is no serious attempt to present a critical analysis of fluorine chemistry nor is any serious distinction made between organic fluorine compounds and fluorocarbon compounds. Most conclusions as to the mechanisms and nature of the chemistry cited are left to the discretion of the reader.

To sum up, this book is in no way an erudite but rather a practical reference book, that furnishes a helping hand to both the neophyte and the practising fluorine chemist to find methods for preparing, handling and using fluorine-containing materials. It could serve as a useful adjunct to the chemist's bookshelf.

Richard Dresdner

A Laboratory Handbook of Pulp and Paper Manufacture

By Dr. Julius Grant. Second edition. (Incorporating the fourth edition of Stevens's "Paper Mill Chemist".) Pp. vii+523. (London: Edward Arnold (Publishers), Ltd., 1961.) 80*s.* net.

PAPER is so common that one forgets that, in comparison with metals, plastics and other sheet materials, it has some very peculiar properties. It is a fibrous assemblage and frequently contains more air than solids; it may vary widely in density, strength and other physical characteristics, and it may be treated with a large range of chemical additives.

This handbook, like Stevens's before it, is written for laboratory workers with some previous knowledge of paper. It should, nevertheless, appeal to a wider range of readers because it effectively summarizes the enormous amount of work put in by chemists into one industry. It outlines the essential pulp and paper processes, then describes, in more detail, the laboratory methods developed for the control of these processes, the analysis of raw materials and the physical testing and analysis of paper. Many methods are only briefly summarized, as numerous references are given to published standard methods, and to the original literature, which is now very large.

It must be difficult to decide what to leave out, and in one sense it is a pity that the book is confined so closely to practical laboratory methods. There is little reference to theory, to the large amount of published work on the visco-elastic properties of paper, or to the development of instruments for automatic control. There are some who believe that chemists have had their day in the paper industry and that the future lies with technologists trained in physics and engineering. Actually co-operation between all three will be essential, but a common ground of theory is vital to this. Even though present theory is incomplete it is a big help in the understanding of the properties of paper and of specifications for it.

There are three misprints in the brief section on statistical method; they would not upset a statistician but might confuse a laboratory worker unfamiliar with that subject. F. Lyth Hudson

Papers on Bacterial Genetics

Selected by Edward A. Adelberg. Pp. xlvi+400. (Boston, Mass.: Little, Brown and Company, Inc., 1960.) 4.50 dollars.

Papers on Bacterial Viruses

Selected by Gunther S. Stent. Pp. xxx+365. (Boston, Mass.: Little, Brown and Company, Inc., 1960.) 4.50 dollars.

THESE companion paper-back volumes are worthy successors to the collection, *Papers in Microbial Genetics; Bacteria and Bacterial Viruses*, selected by Joshua Lederberg in 1951. Yet these two supplementing volumes only reflect a portion of the enormous activity devoted to this field in the decade since the first collection. Of the 51 papers now presented, only five have been retained from the former collection.

To abate the disappointment of many readers who, no doubt, would have selected differently in some instances, each collection is preceded by the selector's introduction, which reviews the main papers on each theme and includes a wide bibliography: on viruses, 13-page review, 164 references; on bacterial genetics, 30-page review, 177 references.

The papers themselves are presented in their original type and style, from which a certain lack of uniformity results; there is dual pagination; but most clearly brought home by this method of presentation is the need for a standard method of reporting references.

The great benefit of this collection is that it provides for the student of microbial genetics a highly concentrated source of information on both the methods and the results of the main workers in this field. Also, the combination of the bibliography in the introduction and at the end of each paper, provides a fairly comprehensive guide to the other sources of related information.

To the specialist, therefore, these two volumes are almost 'essential'. L. B. Quesnel

A Laboratory Manual of Analytical Methods of Protein Chemistry

(Including Polypeptides). Edited by P. Alexander and R. J. Block. Vol. 1: The Separation and Isolation of Proteins. Pp. viii+254. (London and New York: Pergamon Press, 1960.) 50*s.* net.

THIS book is the first of three volumes devoted to practical techniques in the protein field, and contains seven chapters describing various methods for the separation and isolation of proteins. The first chapter (by Keller and Block) surveys the classical methods, such as precipitation with salts and organic solvents, for the separation of proteins. In chapter 2, Okunuki gives detailed descriptions of the methods, due mainly to Japanese workers, for the isolation of cytochromes, and bacterial α-amylase and proteinase. Chapter 3 comprises two sections. The first, by Keller and Block, reviews the techniques of adsorption and ion-exchange chromatography as applied to proteins, while the second, by Peterson and Sober, describes an ingenious variable-gradient device for column chromatography. In the next two chapters, Craig gives a full account of the use of dialysis and partition methods. The book ends with descriptions of the less commonly used techniques of multi-membrane decantation (Polson and Largier) and zonal density gradient electrophoresis (Svensson). It is to be hoped that the value of these methods will now be more widely recognized. Those readers who are not afraid of elementary mathematics will find that the theoretical bases of the various techniques are presented in a manner which does not engulf the practical aspects. A liberal number of plates and diagrams will enable workers in the less-affluent laboratories to construct much of the equipment described. In spite of a number of errors and a rather inadequate subject index, I feel that this volume will be extremely valuable to workers in the field of protein research. D. T. Elmore

An Introduction to the Chemistry of Heterocyclic Compounds

By R. M. Acheson. Pp. xiv+342. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1960.) 5 dollars; 35*s.*

THIS book has the laudable aim of supplying the student with a concise account of the properties and reactions of the more fundamental heterocyclic systems. In this it succeeds admirably. It covers the range from 3- to 6-membered heterocyclic compounds—with oxygen, sulphur, and nitrogen as the hetero-atoms taken singly and (for the larger rings) in pairs—together with their important benzo-derivatives and the fused systems of purines and pteridines. Naturally occurring compounds of relevant interest are discussed briefly or mentioned incidentally, but carbohydrates and alkaloids are excluded. Although the scope is therefore wide, the main theme is the inherent chemistry of the commoner heterocyclic compounds. This is treated in sufficient detail to allow comparisons to be made both within and between the various classes of compound. The presentation is clear and the discussion modern, being supported by pertinent physical data and based on mechanistic principles. Moreover, as befits an introduction, the reader is given adequate guidance to further sources of information.

Such books as this must surely put an end to those perfunctory postscripts with which exhausted writers of text-books usually dispose of the subject. If ultimately this is service enough, more immediately the service to students and teachers is immeasurable.

Theory of Markov Processes

By E. B. Dynkin. Translated from the Russian by D. E. Brown. Edited by T. Kováry. Pp. ix+210. (London and New York: Pergamon Press, 1960.) 60*s*. net.

THIS important and highly original work is devoted to a study of the foundations of the theory of Markov processes. It is written for the professional probabilist, and has little to offer to the non-expert, although any mathematician concerned with the teaching of measure theory will find it worth his while reading Chapter 1, in which the classical material is set out in a new and highly elegant form. This chapter also contains a careful account of conditional probabilities, some information about the new concept of "topological measurable spaces", and the best extension yet of the Daniell–Kolmogorov theorem on the construction of probability measures on function-space. The remainder of the book presents the first thorough formulation of the theory of Markov processes, starting with a whole collection of measures corresponding to all possible initial instants and all possible initial states, and allowing (as is now found convenient) the termination of the process at a random instant. The difficult theory around the concept of a 'strict' Markov process is set out in great detail. The present work is based on lectures given by the author in Moscow and Peking; it will be followed by a further volume devoted to the infinitesimal generators associated with Markov processes. It is very much to be hoped that the publishers will find it possible to translate this also.

D. G. Kendall

Combinatorial Analysis

Proceedings of Symposia in Applied Mathematics, Vol. 10. Edited by Richard Bellman and Marshall Hall, Jr. Pp. vi+311. (Providence, R. I.: American Mathematical Society, 1960.) 7.70 dollars.

THIS volume records the proceedings of the symposium held at Columbia University during April 24–26, 1958. It consists of twenty-four papers and covers a very wide range of topics, including finite geometry, algebra, and number theory in pure mathematics; and statistics, communication theory and transportation in the applied field. A fairly recent development has been the use of an electronic computer to investigate combinatorial problems, and several of the papers describe results obtained. Some of these depend mainly on algorithms and others on somewhat complicated search techniques.

The papers on finite geometries include one by R. H. Bruck on "Quadratic Extensions of Cyclic Planes", one by D. R. Hughes "On Homomorphisms of Projective Planes" and one by A. A. Albert on "Finite Division Algebras and Finite Planes". Those on number theory include a paper by A. L. Whiteman on "The Cyclotomic Numbers of Order Ten" and the paper by O. Taussky and J. Todd on "Some Discrete Variable Computations". Thus pure mathematics is well represented in current activity in combinatorial analysis. But perhaps the main motive for this activity has come from operations research. Thus there is a paper by R. E. Gomory on "Solving Linear Programming Problems in Integers", one by M. Gerstenhaber on "Solution of Large Scale Transportation Problems", and a paper by M. M. Flood on "An Alternative Proof of a Theorem of König as an Algorithm for the Hitchcock Distribution Problem". There is also a paper by R. Bellman on "Combinatorial Processes and Dynamic Programming", and a paper by A. J. Hoffman on "Some Recent Applications of the Theory of Linear Inequalities to Extremal Combinatorial Analysis". These titles are sufficient to demonstrate the dynamic character of present-day research in combinatorial analysis. Anyone who moves in this field will wish to consult the proceedings.

L. S. Goddard

Ciba Foundation Symposium on Quinones in Electron Transport

Edited by G. E. W. Wolstenholme and Cecilia M. O'Connor. Pp. xii+453. (London: J. and A. Churchill, Ltd., 1961.) 60*s*. net.

THIS latest addition to the CIBA Foundation Symposia provides a most welcome review of recent work on the role of quinones in biological systems. As in previous volumes of this series, lectures by recognized authorities in the field are reproduced in full, the charts and diagrams often relating to hitherto unpublished material. Such treatment provides the atmosphere of the seminar rather than the formal lecture room, and the interest is further enhanced by the inclusion of the full discussion (diagrams again reproduced).

A detailed critique of a symposium volume of this type is quite out of place, but biochemists and organic chemists interested in the processes of biological redox systems will find stimulation and many useful references in this work. The symposium consists of the following lectures: isolation chemistry of ubiquinone (R. A. Morton, E. L. Crane, O. Isler and K. Folkers), coenzyme A and electron transport (D. E. Green); oxidation of quinones by mitochondrial preparations (E. C. Slater); oxidative phosphorylation (V. M. Clark, Sir Alexander Todd and P. J. Russell); biosynthesis of quinones (H. Rudney, A. J. Birch, O. Wiss and R. E. Olsen); biosynthesis of terpenoid side chains of quinones (F. Lynan); diet-induced changes in ubiquinone-levels (J. Green); function of vitamin K (C. Martius); spectroscopic observations of the redox reaction of ubiquinone in heart and kidney mitochondria (B. Chance); role of ubiquinone in the respiratory chain (E. R. Redfearn); histochemical studies (L. W. Wattenberg); role of plastoquinone in the electron transport system of photosynthesis (N. I. Bishop).

A. I. Scott

NATURAL RADIOACTIVITY IN TOBACCO AND TOBACCO SMOKE

By DR. V. C. RUNECKLES

Imperial Tobacco Co. of Canada, Ltd., Research Laboratory, Montreal

FROM time to time reports on the levels of radioactivity in tobacco and tobacco smoke have appeared in both the lay and scientific Press. Mulvaney[1], Spiers and Passey[2] and Turner and Radley[3] have reported experimental work on the levels of radioactivity in cigarette smoke, while Ash[4] has calculated figures for the levels of activity in cigarette main-stream smoke based on its potassium content and the natural abundance of the radioactive isotope of potassium (potassium-40).

Interest in the level of natural radioactivity in smoke has come from two directions. First, the suggestion has been made[1] that the natural activity of cigarette smoke, resulting mainly from its potassium-40 content, is a cause of lung cancer. Secondly, interest in smoke activity has been aroused by Ash's claims[4,5] that the level of activity in cigarette smoke is so high that the cigarette smoke can be defined as a radioactive material since, according to his calculations, its specific activity exceeds a level of 2,000 μμc./gm., the basis of the definition according to the British Factories Act[6] and the International Atomic Energy Agency[7].

It therefore seemed desirable to obtain experimental information on the level of natural radioactivity in cigarette tobacco, ash and main-stream smoke, and to compare the observed level in smoke with figures obtained by calculation from its potassium content. Accordingly, plain cigarettes of both Canadian and American manufacture (74 mm. and 70 mm., respectively) were smoked to a butt-length of 23 mm. on a constant-pressure smoking machine, taking a 35-ml. puff of 2-sec. duration at a frequency of one puff per min. Main-stream smoke was collected in a train of three water traps followed by a 'Cambridge' filter. Cigarettes were smoked in batches of fifteen. The 'Cambridge' filter was replaced after smoking two batches. The cigarettes were extinguished with carbon dioxide. A total of 300 cigarettes was smoked in each experiment.

The contents of the traps were combined with washings of water and methylene chloride (to dissolve organic materials), evaporated to dryness in 'Vycor' crucibles and ashed at 450° C. for 18 hr. The residues after ashing were boiled in aqua regia until almost entirely dissolved. The samples were then taken to dryness, dissolved in 5 *N* hydrochloric acid, and aliquots plated on stainless steel planchets for counting.

The 'Cambridge' filters were ashed for 18 hr. at 450° C. and extracted with hot concentrated hydrochloric acid. The extracts were evaporated to dryness, the residues dissolved in 5 *N* hydrochloric acid and plated as above.

In order to determine the amounts of radioactivity present in the cigarettes before smoking, fifteen cigarettes comparable to those smoked were cut to 51 mm. (Canadian) and 47 mm. (American) and exhaustively extracted with water for 5–6 days (Soxhlet). The extracts were dried, ashed and treated as above. Ash collected from the cigarettes smoked in these experiments was digested with aqua regia until almost entirely in solution, dried and treated as already described.

The amounts of activity in the butts were determined as described for the unsmoked cigarettes. The activity present in a 23-mm. length of cigarette before smoking was calculated by proportionality from the values found for the unsmoked cigarettes. Subtraction from the observed activities of the butts led to values for the amounts of smoke activity trapped within the butts.

Measurement of radioactivity was made with a Baird–Atomic model *A*2-2-27*PF* proportional flow automatic counting system using a model 822 detector tube with a 'Mylar' end window and 90 per cent argon–10 per cent methane counter gas.

Because of the low count-rates obtained from the aliquots, and in order to minimize counting errors due to fluctuations in background count-rate, sample and background measurements were alternated, each being counted for the duration 900 counts, and each determination being repeated in sequence 50 times, that is, until 45,000 counts had accumulated per planchet.

The efficiency of the counter for potassium-40 was determined by measuring the activities of weighed samples of potassium chloride (analytical grade). A sample of potassium chloride was dried *in vacuo* over phosphorus pentoxide. Approximately 20 gm. were weighed accurately and dissolved in 100 ml. water containing 0·5 per cent gum arabic. Replicate planchets were prepared by accurately pipetting 200 μl. quantities on to stainless steel planchets, which were dried beneath an infra-red lamp. Half the planchets were placed in a furnace at 450° C. for 18 hr. After heating, all planchets were counted until 14,400 counts had accumulated for each. The mean count-rates for the heated and unheated samples were 7·9 and 7·7 c.p.m. respectively, showing that no losses occurred during heating. The mean sample weight of potassium chloride was 42·58 mgm. and the mean count-rate 7·77 c.p.m. The calculated potassium-40 activity (see below) was 36·1 d.p.m. leading to a counter efficiency value of 21·5 per cent.

The experimental results obtained in this work are presented in Table 1, which shows that almost all the activity present in the unsmoked cigarette can be accounted for in the main-stream smoke, ash and butt. Furthermore, approximately 90 per cent of it

3. American 70 mm.	0·159	21·20	17·90	0·52	88·8	0·75

* Activity of length of cigarette smoked to 23 mm. butt.

appears to remain in the ash, while less than 1 per cent is transmitted to the main-stream smoke. This finding is in agreement with the work of Spiers and Passey[2], who were unable to detect any activity in smoke, and concluded that the activity in the unsmoked cigarette remained essentially in the ash.

As pointed out above, each sample was counted until at least 45,000 counts had accumulated. For this number of counts the standard deviation is less than 0·5 per cent. However, considerably larger errors are associated with the various stages of sample preparation. The largest of these is undoubtedly associated with differences in sample size and thickness, giving rise to differences in sample geometry and self-absorption. While every effort was made to obtain uniform planchets, the pipetting of aliquots of the hydrochloric acid solutions and slurries led to uneven distribution of material.

The data for smoke activity are probably more accurate than those for cigarettes, butts and ash, since in this case sample preparation was more reproducible. However, the actual magnitude of the errors associated with these observations cannot be determined, but it would seem unlikely to exceed 10–15 per cent. In the light of this uncertainty, it is of interest to compare the observed activities for smoke with the value obtained by calculation.

Cogbill and Hobbs[8] found that potassium is the major metallic constituent of main-stream smoke, accounting for 135 μgm. of the 150 μgm. of metals in the smoke of one cigarette. The natural abundance of potassium-40 is 0·0118 per cent[9], and its half-life $1\cdot26 \times 10^9$ years[9], from which a simple calculation leads to a value of 0·113 μμc. as the potassium-40 activity in the main-stream smoke of one cigarette.

The figures for smoke in Table 1 are in general agreement with this calculated value. However, those for the Canadian cigarettes tested are somewhat lower, while that for American cigarettes is higher than 0·113 μμc. The American cigarettes smoked in this work and those used by Cogbill and Hobbs were blends of Burley and American flue-cured tobacco, while the Canadian cigarettes studied consisted exclusively of Canadian flue-cured tobacco. Since American flue-cured tobacco has a considerably higher potassium content than that grown in Canada, the difference in the level of smoke activity is perhaps not surprising.

If the 10–15 per cent figure suggested is a reasonable estimate of the error associated with these observations, it becomes clear that the measure of agreement between observation and theory suggests that the activity detected in main-stream smoke is due almost entirely to potassium-40, rather than to other isotopes, either natural or artificial. As Cogbill and Hobbs[8] point out, it is not surprising that potassium is the major metallic smoke constituent because it is one of the predominant mineral constituents of tobacco, and, as the chloride, possesses a distinct, though low, vapour pressure at the temperature of the combustion zone.

Table 2 lists the specific activities of the cigarettes studied and their main-stream smoke. In the case of the whole cigarettes the values are expressed as μμc./gm. of dry cigarette (tobacco plus paper), while in the case of smoke, the experimental values are expressed in terms of 'whole smoke'. These 'whole smoke' values were determined from the increase in weight of two 'Cambridge' filters in series when 15 cigarettes were smoked under the conditions described above, without the insertion of the water traps.

* Calculated from data of Cogbill and Hobbs (ref. 8).
† Reported by Cogbill and Hobbs.

The values for the specific activity of smoke are of primary interest in connexion with the suggestion that smoke can be defined as a radioactive substance[4]. Unfortunately, the figures on which Ash bases his claims are incorrect since they are based upon his calculated value of 0·01 mμc. of potassium-40 activity in the main-stream smoke of one cigarette. Thus when expressed in terms of 150 μgm. of smoke metals, the specific activity of smoke using the correct value of 0·113 μμc. per cigarette is 0·667 mμc./gm. Ash more recently[5] has used this value rather than the value of 6·67 mμc./gm. quoted in his original paper. However, all these calculations of specific activity are unrealistic since they are based upon the weight of metallic smoke constituents alone. A more reasonable basis for calculation is the weight of whole smoke, exclusive of gases, since the potassium-40 activity of smoke is distributed throughout its particulate matter as a whole. The results in Table 2 are calculated on this basis, and show clearly that the specific activities of the smoke from the cigarettes studied are several orders of magnitude less than the level of 2,000 μμc./gm.

Ash's view that smoke is definable as a radioactive substance[5] thus has its basis in the unrealistic use of smoke metals alone for calculating specific activity. However, his further statement that at 667 μμc./gm. the specific activity of smoke is only one-third of the level of the definition, but that this level should be reduced to one-tenth when applied to the population as a whole is without meaning. His point that it is generally agreed that the levels of radioactivity permitted for occupational exposure are ten times those permitted for the general public is irrelevant when dealing with specific activities; for permissible levels are based upon considerations of total accumulation of irradiation, irrespective of the specific activity of the source. As a consequence, the safety factor of one-tenth cannot meaningfully be applied to the 2,000 μμc./gm. level of the definition[6,7].

In connexion with the view that the radioactivity of tobacco smoke is the cause of lung cancer in the smoker, several questions can be raised. For example, how does the amount of activity inhaled by the smoker compare with his intake of natural activity in the diet ? How does the inhaled activity compare with the equilibrium-level of activity in the body ? How rapidly are mineral smoke constituents eliminated from the lung. How does the level of activity in the particulate phase of smoke compare with the natural level of radon and thoron activity in air ?

Little information is available in the literature on the absolute levels of the naturally occurring isotopes, in contrast to those of the isotopes strontium-89, strontium-90 and cæsium-137 which have come into prominence recently as constituents of 'fall-out'. Table 3 presents a collection of results obtained from various sources. Where so indicated, the levels of

Table 3. NATURAL RADIOACTIVITY IN MAN'S ENVIRONMENT

Cow's milk	0·01 μμc./ml.	10

* ^{40}K activity of the potassium contents of these foods, calculated from the data of ref. 11.

activity are for potassium-40 alone, and are calculated from potassium content. A comparison of the results from Tables 2 and 3 shows that the specific activity of the unsmoked cigarette is higher than the specific activity of any of the foodstuffs listed, which were selected to cover a wide range of potassium contents. This difference is, however, to be expected, since tobacco has a relatively higher potassium content than most food crops because of the fertilization practices used in its cultivation. In addition, the tobacco in the cigarette is in a partly desiccated form, and it can be seen that the level of its activity is approached by those of the two dry food materials listed, namely, dried apricots and wheat bran.

Relating the level of smoke activity to total uptake of activity by the body, it should be emphasized that all food materials contain natural radioactivity to some extent. The average dietary intake of activity is difficult to estimate since it depends so much upon the nature of the diet, geographical location and, more recently, upon the contamination of foodstuffs by 'fall-out'. Mayneord[12] has shown that approximately 20 per cent of the dose-rate received by the body arises from its potassium-40 content, while external sources such as cosmic radiation and local radiation from the ground and building materials provide approximately 70 per cent. Internal radiation from isotopes other than potassium-40, for example, carbon-14 and the radium, thorium and uranium series, probably gives rise to less than 5 per cent of the total body irradiation.

Since experimental evidence suggests that potassium is by far the most important isotope in smoke, and since this same isotope is the major source of internal radiation in the body, it is of interest to look at the average diet from the point of view of its potassium-40 content.

The figures in Table 4 are calculated from values for daily potassium intake in the United States published by Anderson *et al.*[14]. Of the daily uptake of approximately 3 gm. potassium (2,560 μμc. potassium-40), 2·6 gm. (2,180 μμc. potassium-40) are excreted daily in the urine, while the remainder is eliminated in the fæces and sweat. The rate of total elimination is determined by the need to maintain an average bodily equilibrium level of approximately 133 gm. potassium (120 mμc. potassium 40) (ref. 12).

Table 4. DAILY POTASSIUM INTAKE, BASED ON *per capita* FOOD CONSUMPTION IN THE UNITED STATES

Source	Potassium (gm./day)	Potassium-40 (μμc./day)
Dairy products	1·15	960
Meats	0·46	390
Flour and cereals	0·20	170
Vegetables	0·56	470
Citrus fruits	0·10	80
Potatoes	0·59	490
Total	3·06	2,560

The calculated potassium-40 activity of cigarette smoke (0·113 μμc. per cigarette) is a very small fraction of the dietary intake, and, even in the case of the heavy smoker, smoking, say, 50 cigarettes a day, the intake of potassium-40 from smoke would be less than 0·25 per cent of the daily intake from food.

However, this extremely small amount of activity could be important if the potassium-40 remained in the lung for a long period, that is, if the lung accumulated mineral smoke constituents, including potassium, without elimination or absorption.

Table 5. FATE OF PARTICULATES IN RESPIRATORY TRACT IN STANDARD MAN

Distribution	Readily soluble compounds (per cent)	Other compounds (per cent)
Exhaled	25	25
Deposited in upper respiratory passages and ultimately swallowed	50	50
Deposited in lungs	25 (taken up in body fluids)	25 (12·5 per cent eliminated in first 24 hr.; remainder eliminated with a half-life of 120 days into body fluids)

Table 5 shows the fate of particulate matter in the respiratory tract as calculated for the standard man[15]. This indicates that, in general, soluble particulate matter is deposited in the lung to the extent of about 25 per cent and is then absorbed into the blood stream. Less-soluble materials are deposited to about the same extent, but about half of these are eliminated in one day while the remainder have a biological half-life of about 120 days. Since the potassium in smoke is likely to be in a readily soluble form, it would seem probable that it is eliminated quite rapidly. The work of Wolff and Purdom[13] suggests that this is so. They allowed dogs to inhale tobacco smoke containing various metal tracers and determined the level of activity of these tracers in the lung tissue at intervals after the smoking period. In the case of potassium-42 they found that nearly all activity disappeared from the lung during the smoking period or soon thereafter. Since potassium-40 and potassium-42 are chemically identical, these results suggest that potassium-40 taken into the lung during smoking is also rapidly eliminated from that organ.

These results combine, therefore, to suggest that cigarette smoking does not overburden the body from the point of view of irradiation by potassium-40, nor does it produce an appreciable increase in radiation to the tissue of the lung.

Relevant to this last point, it is of interest to compare the intake of potassium-40 activity from smoke with the natural activity of air, due to its content of radon and thoron. These gases decay with the production of heavy metal isotopes and in the process emit α-particles which are much more damaging to tissue than the β-particles of potassium-40. On the basis of 11 puffs of 35 ml. vol. in the case of the Canadian cigarettes smoked in this work, the specific activity of their main-stream smoke can be calculated as approximately $2 \cdot 4 \times 10^{-4}$ μμc./ml. In the case of the American cigarettes,

Appearing in July

A Course of Mathematics for Engineers and Scientists

C. PLUMPTON and B. H. CHIRGWIN, *Dept. of Mathematics, Queen Mary College, London*

Appearing this month is Volume I of this 7 volumes series covering the mathematics required by Science and Engineering Students during their undergraduate studies. The earlier volumes lead on from A level mathematics, while the later volumes are concerned with more advanced topics and methods used in science and engineering, and, with application, to classical mathematics. In the later volumes the honours student will find much that he will need in his studies. The emphasis throughout is placed on mathematical methods and their application to physical problems.

Volume I 350 pages illustrated Approx. 30s.

The Brain as a Computer

F. H. GEORGE, *Dept of Psychology, University of Bristol*

This important volume represents the first serious attempt to apply cybernetics to the problems of cognition. The emphasis throughout is on methodology, and attempts to provide a methodological framework within which cognitive problems may be tackled. The problems themselves are discussed also in terms of current neurophysiological evidence.

480 pages illustrated 63s. net ($9.50)

Progress in Materials Science (formerly *Progress in Metal Physics*)

Editor BRUCE CHALMERS

Volume 10, Paper 1 *Alloy Phases of the Noble Metals*

T. B. MASSALSKI and H. W. KING, *The Mellon Institute, Pittsburgh*

A valuable review of the experimental and theoretical developments in the noble metals and their alloys within the framework of the theory of alloys. Particular attention is devoted to phases with close-packed hexagonal structure, and reclassification of alloy phases.

77 pages illustrated 25s. net ($3.50)

Handbook of Numerical Methods for the Solution of Algebraic and Transcendental Problems

V. L. ZAGUSKIN

This book, translated from the Russian, will be extremely useful to engineers having no special mathematical qualifications, as the treatment of the material is not burdened too much with mathematical abstraction. The practical engineer will welcome the comparisons between the different methods given in the book and the Author's recommendations regarding the use of different calculating instruments.

216 pages 40s. net ($6.50)

Photometric Titrations

J. B. HEADRIDGE, *Dept. of Chemistry, University of Sheffield*

Photometric titration technique is discussed and reviewed from its introduction in 1928 up to the present day, covering all recent advances in the field. The book contains chapters on theory, apparatus and the application of photometric titrations in acid-base, oxidation-reduction, complexometric, precipitation and miscellaneous systems as well as a chapter on photometric end-point detection in coulometric titrations.

122 pages illustrated Approx. 40s. ($6.50)

Surface Phenomena in Metals and Alloys

V. K. SEMENCHENKO Edited by R. KENNEDY, *Royal College of Science and Technology*

This book, translated from the Russian, is concerned with the physics of certain surface phenomena, especially surface tension and adsorption, as manifested chiefly by pure metals and alloys, and explains the theory underlying these phenomena. A useful set of tables with data for a number of metals, many of them comprising the results by different authors, is appended.

approximately 9 puffs were taken per cigarette, leading to a figure of about 5×10^{-4} μμc./ml. The levels of radon–thoron activity in air are shown in Table 3. Using Mayneord's value of 3×10^{-4} μμc./ml., it is apparent that the levels of potassium-40 activity in smoke are of the same order of magnitude.

Further to this, Turner and Radley[3] have studied the α-particle activity of tobacco, due to its radium and thorium contents, and have concluded that the release of α-activity during smoking is extremely small. They state that even in the case of the heavy smoker, the additional α-activity taken into the lungs is less than 1 per cent of the atmospheric radon and thoron inhaled daily by any individual, approximately 2 mμc., a figure obtained from the approximate daily uptake of air, 2×10^{7} ml. (ref. 15) and its radon–thoron content, 3×10^{-4} μμc./ml. (ref. 12).

In summary, therefore, we can say that the observed activity of cigarette main-stream smoke appears to be due almost entirely to its content of potassium-40. The amounts of this activity taken into the lung, even by the heavy smoker, are minute compared with the bodily uptake from the diet, and are rapidly eliminated from the lung tissue. In addition, this potassium-40 activity only exceeds by a small amount the α-activity taken into the lungs of all individuals because of the radon and thoron in the Earth's atmosphere.

Finally, calculations of the specific activity of smoke, based upon a logical appreciation of its nature, lead to values far below the internationally agreed level at which any material can be defined as radioactive.

I wish to thank the Directors of the Imperial Tobacco Co. of Canada, Ltd., for permission to publish this article, and to acknowledge the assistance of Mr. B. J. Stirling and Mr. K. Woolrich in the experimental work.

CLIMATE AND WEATHERED KARROO DOLERITES

By Dr. H. H. Weinert

National Institute for Road Research,
South African Council for Scientific and Industrial Research, Pretoria

Introduction

A very important road-building material in large parts of the Union of South Africa is Karroo dolerite, the weathered rock being used in the layers of road foundations and the fresh rock when crushed for surfacing chips. The performance of weathered dolerites is known to vary in different parts of the country. The material performs well in the western portion of the Union and badly in the eastern, the differences in performance being borne out by observation that the rate of alteration of the materials, after being placed in the road foundation, appears to increase. These facts led me to carry out research on the influences of environmental conditions on the alteration of basic igneous rocks with particular reference to Karroo dolerites.

The most conspicuous feature of the South African Karroo system is the huge mass of crystalline igneous rock which is called traditionally 'dolerite'; according to present nomenclature, however, it should be designated as 'diabase' of a very wide variety[1]. These dolerites are intrusive into the sediments of the Karroo era in numerous thin dykes and in sills up to a thickness of 200 m. or more. There is a marked southern limit to the extent of these rocks, crossing the southern portion of the Karroo areas in a roughly west–easterly direction (Fig. 1).

The rocks are dark-coloured generally, varying due to structure, texture and mineral composition from norite to quartz-diorite, with diabase forming the bulk of the whole occurrence. Differentiation may lead to light-coloured rocks exceptionally.

Weathering of Dolerites

Dolerite outcrops in the eastern parts of the Union of South Africa show a succession of weathering products consisting normally of four layers which can be distinguished readily by their colour and consistency. The lowest layer is the fresh rock or that which, in comparison with the rest, may be termed

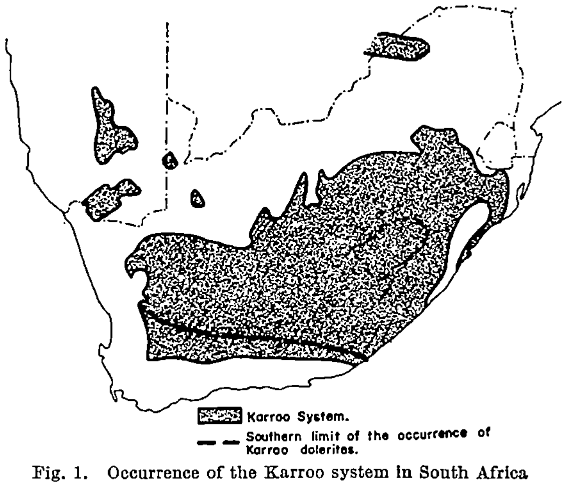

Fig. 1. Occurrence of the Karroo system in South Africa

'fresh'. This rock is dark in colour with the whitish feldspars standing out clearly in the brownish- to greenish-black matrix which consists of pyroxene, amphibole, different ores and occasionally olivine, biotite and quartz. The rock is hard and dense, giving a metallic ring when struck with the hammer. The next layer, the weathered rock, is still hard but brittle, breaking readily when struck with the hammer, and often showing exfoliation. The colour is brownish due to frequent staining with iron oxides. The feldspars are still clearly recognizable, while most of the mafic minerals have lost their dark colour. The third layer, the badly weathered rock, has lost its consistency completely and become a brittle to soft, yellowish-grey mass with an earthy feeling. The original structure of a crystalline igneous rock is still preserved, and the former planes of exfoliation are clearly visible: most of the original minerals, however, have lost their properties completely. The fourth layer is the residual soil on the top of such deposits. These soils vary, depending on climate and relief, being black clays in water-logged areas in most cases and deep red clays on slopes[2].

The weathering succession in dolerite outcrops in the western portions of the country differs somewhat from the profile given in the previous paragraph. The stages 'badly weathered' and 'residual soil' are not properly reached and the whole succession remains in the state 'weathered', as defined. However, the rock does not remain a hard material but merely disintegrates, finally becoming a dolerite gravel, the grains of which are the different minerals of the original rock, showing only partial chemical alteration. Physical weathering is clearly overshadowing chemical weathering in the western portions of the Union, this statement being in some contrast to others made previously[3].

An increasing amount of sand normally occurs towards the surface, being blown in, and consequently mixed with, the residual soil. The difference between clays, black or red, in the eastern parts of the country and sandy to gravelly soils with only little clay, is also expressed by the predominance of the soil clay minerals in the widest sense. Hydrous mica is predominant in the west, and other clay minerals, montmorillonite and kaolin in particular, in the east[4].

A statistical investigation on the percentage of secondary minerals in the different layers of the weathering successions has been carried out for a number of samples from different sites. Similar investigations had been made previously on certain basalts in Oregon, United States[5]; the South African approach is different from the American one in so far as the latter dealt with rocks from rather uniform environments in regard to topography and climate, while the South African investigation has covered materials from many different regions.

Quartz, feldspar, biotite, amphibole, pyroxene, olivine and magnetite were considered primary minerals and all others as secondary. The investigation was carried out with a polarizing microscope and counting was done with the aid of a micrometer. Special difficulties were experienced during the preparation of the badly weathered parts and the residual soils of the weathering succession. For grinding purposes, resins had to be used in order to harden these materials. All minerals which could be recognized individually were counted separately, and those too small for recognition under the microscope, such as clay minerals, were just counted as 'secondary'. The results of counting were arranged in two groups, primary and secondary minerals, and the relation was expressed as a percentage of the total number counted.

The results were compared with the field description of the weathering succession as 'fresh', 'weathered', 'badly weathered' and 'residual soil', and a remarkably good correlation of these designations with certain ranges of percentages of secondary minerals was observed:

Field description of rock	Percentage of secondary minerals
Fresh dolerite	< 25
Weathered dolerite	25–32
Badly weathered dolerite	> 32
Soil, residual from dolerite	> 70

The small range, 25–32 per cent, for the section 'weathered dolerite' appears to be the most remarkable result of this investigation, because it shows that the transition from the solid, fresh-looking rock to the thoroughly decomposed material seems to be a rather abrupt change. The number of samples studied so far has not allowed a range of percentage to be allocated to the group 'badly weathered'; the limit between 'badly weathered' and 'residual soil', however, may be expected somewhere between 60 and 70 per cent.

X-ray investigations have shown that montmorillonite and hydrous mica occurred in all samples, including those which were classified as 'fresh'. Montmorillonite is well crystallized in these samples and also in some of the 'weathered' and 'badly weathered' ones; it never appeared crystallized in the residual soil, but only as amorphous material. The transition from the crystallized to the amorphous states appeared to take place in the stages 'weathered' and 'badly weathered'. Kaolin may occur suddenly at a certain level in the 'badly weathered' stage, being then associated with an almost complete disappearance of all feldspars.

The results of the work on secondary minerals, as well as from X-ray and differential thermal analysis investigations, were the same for samples from the western and the eastern portions of the country as regards the classification from 'fresh' to 'residual soil'. In the western part of the country, however, the state 'weathered' was not passed.

Standard engineering tests carried out on those weathered dolerites which were intended for road construction indicated a regional distribution of the results. This was the case for the Atterberg limits in particular, where the liquid limit and the plasticity index were of special significance and importance. A line could be drawn across the Union with the values of 30 for the liquid limit and 10 for the plasticity index, larger values predominating to the east and lower values to the west of this line. This line intersected the coast line near Port Alfred and crossed the Orange Free State a little east of Bloemfontein; it then continued towards Rustenburg in the Transvaal, following thus a generally north–south course. This also agreed roughly with the types of weathering given above, disintegration prevailing on the western and decomposition on the eastern side of it.

Climatic Investigations

The Union of South Africa falls within three major climatic regions. They are the summer rainfall areas which cover the largest parts of the country, the winter rainfall areas of the Cape of Good Hope and the almost constantly dry desert regions of the north-west. There are remarkable variations within the large summer rainfall areas, concerning the duration of the rainy season and the quantity of water precipitated. The climatic investigations were concentrated on the summer rainfall areas because only those areas are bisected by the line which separated weathered doleritic materials on the basis of the Atterberg limits and which also agreed with the boundary between the types of weathering.

The Orange Free State was chosen for the first detailed investigation for three reasons: (1) the Orange Free State falls completely within the summer rainfall area; (2) the province is relatively small and in a central position within the country; (3) weathered dolerites are almost the only road-building materials within the province and a sufficient number of test results was available.

The climatic investigation included precipitation, potential evaporation calculated for a shallow free-water surface from the Meyer formula[6], relative humidity, wind speeds, temperature and a calculated ratio of evaporation to precipitation. All investigations were made for the months of January (rainy season) and July (dry season) separately, giving thus separate pictures for the climatically extreme parts of the year. The annual precipitation and a ratio of the relative humidities of January to those of July were also added.

The evaporation precipitation ratios were calculated so that the higher value was always divided by the lower one, giving results representing either a surplus of evaporation over precipitation (positive values) or the opposite (negative values); the numerical figures then are comparable. Contours were drawn on the basis of the values obtained, the contour 1·0 connecting places with equal evaporation and precipitation. The contour +3·0 for January appeared to be the most significant in comparison with the lithological boundaries.

Contours were drawn for each climatic indicator, the general contour pattern being compared with the boundary obtained from the test results. Those contours which agreed with this boundary were selected. The most remarkable feature of the results was that, while none of the contours referring to July agreed with the soils boundary, agreement was found for the January values and, furthermore, that all climatic indicators showing an agreement had something to do with water. Besides these monthly values, a close agreement occurred with the annual isohyet of 500 mm. and with a contour connecting all those points where July has the same relative humidity as January. This contour runs a little west of the zone occupied by the other contours. It appears to be of importance, as the Orange Free State falls completely within the summer rainfall area, where January would be expected to be more humid than July. However, the relative humidity of July is higher than that of January in the country west of this line. This fact indicated that the inflow of moist air in January is not high enough to compensate for the higher temperatures in this month.

Climatic and soils boundaries in the Orange Free State. – – –, Relative humidity of 55 per cent in January; + +, relative humidity in January = relative humidity in July; ——, 85 mm. isohyet for January; — —, evaporation/precipitation ratio + 3·0 in January; ○, boundary between hydrous mica (west of line) and other clay minerals (east) as predominant soil clay minerals; ■□■, 500 mm. isohyet of annual precipitation; *LL*, liquid limit; *PI*, plasticity index

The border between the predominance of hydrous mica and other clay minerals in South African soils as indicated by C. R. van der Merwe and H. Heystek[4] was also added. This border runs somewhat west of that defined by the Atterberg limits, which may be one indication that a certain percentage of clay minerals, montmorillonite in particular, must be present in the unsound weathered dolerites to make them differ from the sounder materials of another region.

The position of all these contours, relative to the subdivision of the weathered dolerites in the Orange Free State based on the Atterberg limits, is shown in Fig. 2.

These investigations were then extended over the whole Union of South Africa and contours were drawn again. The same climatic values as for the Orange Free State were sorted out and it was noted that their meaning was the same as before in the eastern Cape Province and the western Transvaal, the whole of Natal being east of the critical boundary. All contours then enter the Bechuanaland Protectorate. From 25° S., however, the 500 mm. isohyet of annual precipitation, together with the boundary of hydrous mica as the predominating soil clay mineral, turns east and re-enters the Transvaal again, but the others retain their approximate northerly direction (Fig. 3). This course of the contours leaves the deeply weathered Bushveld norites—the depth

of weathering is known to be more than 8 m.—on the eastern side of the zone created by the climatic contours. Dolerites do not occur in this part of the Union, but the norites can, however, be considered sufficiently similar to them for such comparison.

Assuming that the effect of water on weathering will increase if evaporation is reduced considerably, a separate investigation on precipitation, evaporation and the ratio of evaporation to precipitation was carried out for the night hours of January, that is, the period 1900–0500 hr., and July, that is, the period 1700–0700 hr.

Contours were again drawn for precipitation, evaporation from a shallow free-water surface and the ratios of evaporation to precipitation. The contour patterns of these three indicators, separately drawn for January and July, were compared with the soils boundary as obtained from the Atterberg limits and it was found that all patterns for January agreed with this boundary, but there was no agreement with the July contour patterns. Those January contours which agreed best with the soil boundaries were selected and used as critical values for the climatic effects on weathering. These critical values were: (1) evaporation during night hours 50 mm., its effect on weathering being greater with decreasing values; (2) precipitation during night hours 30 mm., its effect on weathering being greater with increasing values; (3) evaporation/precipitation ratio during night hours of 1·0, that is, evaporation equal to precipitation. A greater influence on weathering would be expected where surplus of precipitation occurs.

In order to gain an overall picture, numerical values were allotted to all areas of the country on the base of the above subdivision. These were 0 for weak and 1 for strong effects on weathering of the individual climatic conditions during night hours[7]. This evaluation led to the subdivision of the country into six different zones, each one designated by one of the numerical values 0, 1, 2, 3, 4 and 5 (Fig. 4), which means that the higher the numerical value of a given area the stronger the potential influences of all climatic indicators. Two relatively narrow zones, one of them bisecting the summer rainfall area and the other bordering the winter rainfall area of the Cape, have the value 3. The 3-zone of the summer rainfall area agrees well with the full-day contours, as already known from the Orange Free State, as well as with the soils boundary defined from the Atterberg limits and from the predominance of either disintegration or decomposition for that portion of its course which passes the western Transvaal, the Orange Free State and the eastern Cape Province. This zone becomes ill-defined in its northern continuation through the Transvaal, where the easterly type of weathering is known to cross this zone near Rustenburg and Brits, and here the 2-zone seems to take the place of the 3-zone. No conclusion can be drawn about the relevance of the 2-zone in the winter rainfall area of the Cape, where the bulk of rain falling during the colder part of the year might have a somewhat different effect on the weathering of basic igneous rocks. It may be mentioned, however, that more intense weathering of dolerites is known to occur in the vicinity of Calvinia, which is near the 3-zone.

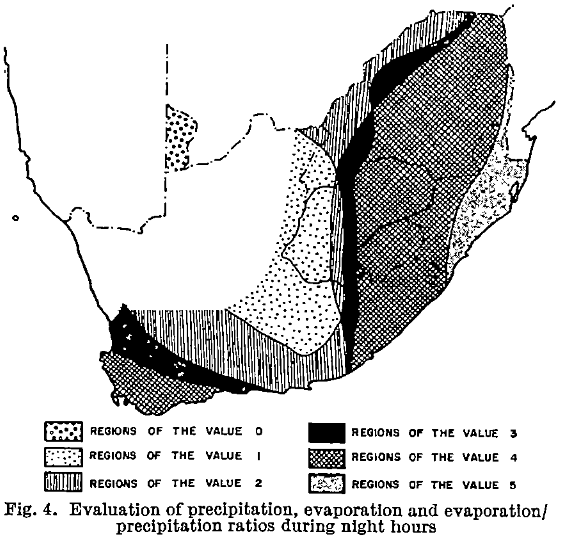

Fig. 4. Evaluation of precipitation, evaporation and evaporation/precipitation ratios during night hours

Conclusions

The comparison of the present climatic conditions of a country with very marked differences between a humid, warm and a dry, cool season, with the types of weathering and with some engineering properties of weathered basic igneous rocks, dolerites in particular, has emphasized clearly the importance of water. All climatic indicators which had an apparent bearing on weathering referred to the climatic conditions of the warmest and most humid month, and all of them were connected with the direct or indirect influences of precipitation or water. The close agreement of a number of climatic contours, demarcating regions with different types of weathering and, at the same time, with different engineering performances of the weathered materials, holds for the larger portion of the South African summer rainfall area. This climatic zone, however, becomes ill-defined towards the north, where increasing mean air temperatures as well as increasing soil temperatures might strengthen the influence of water, that is, a smaller amount of water at a warmer temperature may have the same effect on weathering and on engineering properties as a higher amount of water at lower temperatures. In the winter rainfall areas of the Cape Province no such close agreement of the various climatic contours occurred. A larger temperature effect may also appear here, because the rain falls during the colder part of the year.

Microscopic and X-ray investigations showed that the material alteration which the dolerites undergo during weathering is the same on either side of the climatic separation zone. The percentage of secondary minerals and the type and state of clay minerals were the same, independently of the local climate, if a certain state of weathering were reached.

The rate and progress of weathering, however, can be connected with the local climatic conditions. In the western parts of the country, that is, in the climatic zones 0 and 1 (Fig. 4), decomposition is reduced in favour of mere disintegration and does not normally pass the state 'weathered' of the climatic zones 4 and 5. In the eastern parts of the Union, that is, in the climatic zones 4 and 5, little disintegration occurs and the process of weathering is largely chemical in nature. The 2- and 3-zones are largely transition zones between the other two.

The differences in weathering also refer to the performance of the weathered materials if used for road-construction and, especially for foundation purposes, with decomposition leading to unsound materials and poor results, and disintegration leading to sound materials.

The climatic conditions of a given site or area, the amount of water available in particular, and probably also a combination of air and soil temperatures, may thus provide a means for defining the probable type of weathering and also for predicting the engineering behaviour of weathering or weathered basic igneous rocks, among which the Karroo dolerites are of great practical importance in South Africa.

MAGNETIC STORMS IN INTERPLANETARY SPACE AS OBSERVED BY *PIONEER V*

By EUGENE W. GREENSTADT

Space Technology Laboratories, Inc., Los Angeles, California

IN a preliminary report on the magnetometer experiment carried by the deep space probe *Pioneer V* (1960α), Coleman *et al.*[1] display a correspondence between fluctuations in average ambient magnetic field value at the probe and local a_k magnetic index values recorded concurrently at Fort Belvoir, Virginia, for the very active period March 30–April 3, 1960. Fig. 2 of their paper exhibits the satellite data and the a_k index plotted in parallel, showing agreement between the two traces for the intense magnetic perturbation of April 1 and for lesser events of March 31, April 1 and April 3. The present article extends the comparison between effects at the Earth and at *Pioneer V* over the entire period of regular acquisition of data in the interplanetary region, showing a correlation between 'storms' appearing at the two bodies, and between the interplanetary field and planetary magnetic index, a_p.

The trajectory of *Pioneer V* is shown in Fig. 1. Only field magnitude perpendicular to the axis of rotation of the spin-stabilized probe (arrows) was measured, and only relative changes in the measured component are considered here. Details of probe and magnetometer geometry have been published elsewhere[1,2].

Launched on March 11, 1960, the probe reached a distance of 500,000 km. by the middle of March 12, placing it well outside the terrestrial magnetic field[1,3,4]. The distance between the payload and the Earth increased continuously to approximately 12,000,000 km. on April 30, after which telemetry transmission became too infrequent for significant addition to the results.

Measurements were transmitted as several discrete messages each day, with each message averaging 30 min. duration and including many individual magnetic field readings. Individual readings were averaged over intervals of half a day for this work. The half-day interval has proved to be a convenient unit because it is long enough to diminish the influence of short-term transients, while not so long as to obscure the correlation between short magnetic storms. A smoothed graph of the data has been produced in turn by plotting, instead of each half-day field average $\bar{B}_i$, the mean of $\bar{B}_{i-1}$, $\bar{B}_i$, and $\bar{B}_{i+1}$. The upper curve of Fig. 2 presents this smoothed version of the average ambient field component at the payload, with concurrent geomagnetic storm periods and smoothed planetary indices below for comparison.

The magnetic index curve was prepared in the same manner as that used for payload data: the 3-hr. planetary index a_p, converted from published K_p values[5–7], was averaged over half-day intervals and a three-interval mean applied to the half-day averages.

Periods designated as separate geomagnetic storms by one or more reporting observatories[8,9] are represented in Fig. 2 by solid horizontal bars. Dashed bars appear in connexion with the March 14 event, where there is substantial disagreement on duration of the storm and later where some observatories reported single long events rather than separate occurrences.

Statistical correlation between payload field increase and separate geomagnetic storm incidence is particularly striking. The curve of smoothed payload

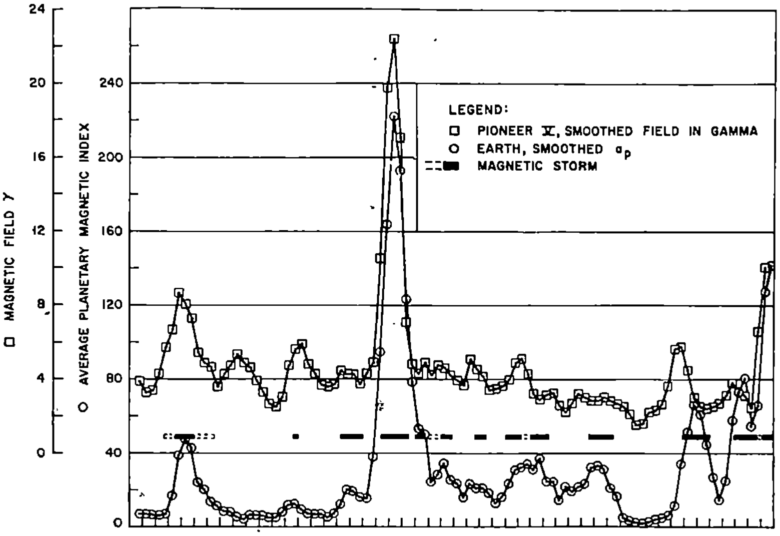

Fig. 2. Smoothed *Pioneer V* magnetic field, smoothed planetary index a_p, and geomagnetic storms

ambient field, characterized by a sequence of crests or excursions of diverse amplitude and more or less similar shape, has 14 maxima and a rapid rise before the graph terminates on April 30. Subsequent data, not shown, give a return to nominal field readings on May 1, so that a fifteenth peak may be added to those visible in the figure.

Of the 15 maxima in the satellite data, 14 are accompanied closely or followed within one day by the occurrence of magnetic storms at the Earth. Of the total of 13 individually reported geomagnetic storms occurring during the fifty days of observation (solid bars) every one is accompanied or preceded within a day by an excursion of the smoothed ambient field at the payload. The geomagnetic storm in the interval April 16–18 can be associated with a pair of local submaxima in the smoothed payload data, making as before a total of fourteen correlated peaks at the probe. The one exception to the agreement between probe data and storm reports is the excursion of March 19–21, but examination of magnetic records covering this interval shows that while no magnetic storm appeared in the reference list, disturbances in the Earth's field, noted particularly on College, Alaska, magnetograms, appear to have taken place (see discussion of magnetic index following).

The plot of smoothed planetary index in Fig. 2 consists of a series of irregular excursions comparable to those appearing in the *Pioneer V* curve. Qualitative agreement between the two measurements can be seen at once, with the extreme maxima of April 1 and 30 as outstanding parallel features. Some details of the March 30–April 3 period have been lost by smoothing, but evidence of correlation for separate peaks of April 1 and 3 can be found in the preliminary report mentioned earlier[1]. Once again, the payload excursion of March 19–21 appears uncorroborated at the Earth, despite the faint trace of corresponding activity in the planetary index. Indication of high-latitude terrestrial effects on March 19 and 21 is present, however, in magnetic indices from College. This can be seen in a comparison of the payload daily average field and College A_k index, reproduced in Fig. 3 for the interval March 12–28.

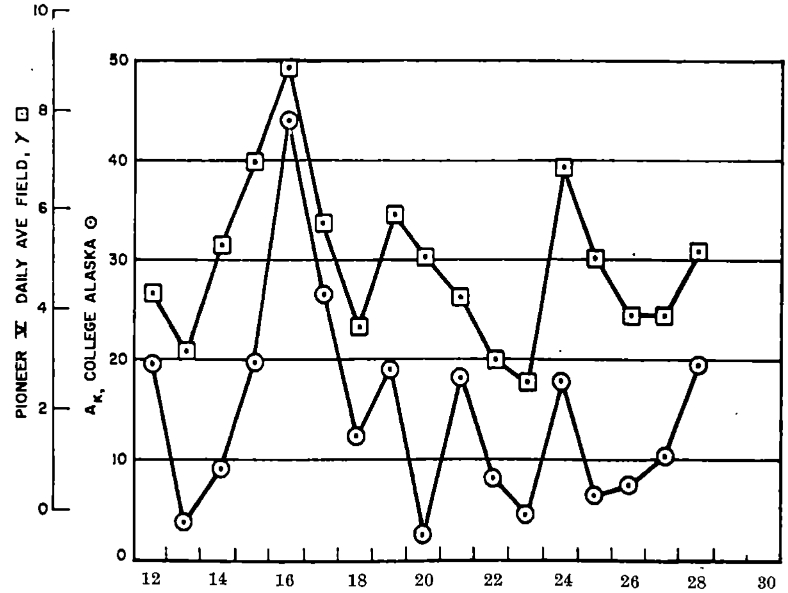

Fig. 3. *Pioneer V* daily average field and daily magnetic index A_k, College, Alaska

The data discussed here and presented in Figs. 2 and 3 show that relative increases in the average value of field amplitude measured by *Pioneer V* almost always occurred in approximate conjunction with magnetic storms at the Earth's surface and consistently with increases in irregularity of the Earth's field as measured by the magnetic indices a_p and A_k. It is tentatively concluded from this evidence that enhancement of at least one component of nearby interplanetary magnetic field regularly accompanies terrestrial magnetic storms. It is also concluded that this enhancement cannot be restricted exclusively to a component directed along radial lines from the Sun, since during an appreciable part of the observation period the probe magnetometer measured field magnitude in a plane nearly normal to the Sun-payload radius (normal to the arrows of Fig. 1).

A feature essential to the correlations between payload and planetary index curves and between payload maxima and terrestrial storms is the assumed correspondence of time-displaced events near the end of April. Preliminary comparison of unsmoothed data with terrestrial observatory magnetograms indicates that the extreme phase difference discernible in Fig. 2 for 'corresponding' events between April 21 and 29 cannot be accounted for entirely by the smoothing process, but is a real feature of the observed interplanetary and geomagnetic fields. Examination of unsmoothed data has also revealed that terrestrial effects were either delayed or persisted longer than corresponding interplanetary disturbances for some events earlier in the history of the flight, although never with phase differences as large as that seen late in April.

An increasing delay toward the end of the period of acquisition of data might be expected to result from the steadily advancing distance between Earth and probe, on the assumption the satellite was intercepting disturbances of solar origin travelling toward the Earth. However, based on the approximate 1,000 km./sec. average velocity usually inferred for transient solar-terrestrial magnetic effects, the expected delay between *Pioneer V* and the Earth, even for distances in effect at the end of April, would be less than 3·3 hr., and thus imperceptible in the scale of Fig. 2. Long delays due solely to increase in time of probe-Earth passage would require local velocities close to 100 km./sec. to account for the observed shifts, therefore ruling out solar effects moving by the payload at ten times this speed.

Suggested interpretations of the time displacements include a low payload-Earth velocity and a terrestrial delay mechanism, and the possibility that excursions observed in the interplanetary region and at the surface of the Earth are related respectively to different phases of the travelling storm phenomenon. Further investigation of the data is now in progress.

Acknowledgment is due to Dr. E. J. Smith and Dr. J. M. Kelso for useful discussions and to M. Saxe for help in preparation of the data used above. P. J. Coleman, jun., was responsible for reduction of the *Pioneer V* magnetic data.

The programme is sponsored by the United States National Aeronautics and Space Administration.

OBITUARIES

Prof. W. T. Astbury, F.R.S.

With the death of Prof. W. T. Astbury on June 4, at the age of sixty-three, the world of crystallography, fibres and molecular biology lost an international figure.

A product of the 'Five Towns', eldest son of a large family, versatility at Longton High School earned a scholarship to Jesus College, Cambridge, where, with a break by service in the Royal Army Medical Corps, he graduated in physics in 1921.

The first phase, 1921–28, of his working life was one of tutelage and growth as assistant to Sir William Bragg, first at University College, London, then, from 1923, at the Davy Faraday Laboratory of the Royal Institution where "in that dawn 'twas bliss to be alive", the happy coterie including Müller, Shearer, Bernal, Yardley, Robertson, Robinson and Cox. There he learnt the lessons of simple and direct experiment, the fine tradition of 'Friday Evening' exposition, the value of collaboration. Notable early work on essential systematics and technique of X-ray crystal analysis were the famous space-group tables with Yardley and the α-ray integrating photometer. Bold attempts at key structures like tartaric acid and the acetyl acetones were necessarily sketchy; introduction to his life-work came in preparing fibre X-radiograms for Bragg's lectures "On Common Things".

In 1928, Astbury found a field ready for his talents as lecturer in textile physics, University of Leeds, Bragg sustaining him in early difficulties. Five years solid work produced papers in the *Philosophical Transactions of the Royal Society* on the structure of hair, wool and related fibres which laid for a generation the foundations of high-polymer structural studies. Briefly, inspired analysis of the vague X-ray diffraction pictures of biological fibres under varied conditions of humidity, temperature, tension and chemical treatments, related to optical, mechanical, chemical and technical features, led to a broad scheme of keratin structure: the $\alpha \rightleftharpoons \beta$ polymorphic transition as reversible intra-molecular chain folding, the folds plausibly related to side-chains and S—S links to explain 'set' and supercontraction. This brought academic and industrial recognition, welcome financial support, and award of the Royal Institution's quaintly worded Actonian Prize.

Extension to muscle and collagen established two broad classes of fibrous protein structure, while similar work on egg albumen and on protein layers emphasized chain folding as a key to fibrous and globular protein relations. These, with *ad hoc* studies of dyeing and tanning and his 'missionary' *Fundamentals of Fibre Structure*, impressed old trades with new knowledge. It was the creative period.

When not abroad, the rest of his life, from 1955 in doubtful health, was spent in Leeds developing such themes, as reader in 1937 (later honorary) and, from 1945, as professor of biomolecular structure. Polypeptides, cellulose, alginates; the vital structures of flagella, nucleic acids, muscle components; excursions on the abnormalities of cancer, influenza, rheumatism or '*pili torti*'; new tools; all was his oyster. About 150 publications in some thirty journals indicate his range and energy. His star shone brightly afar, attracting in all benefactions exceeding £100,000. Rather silent among his peers, he yet gave generous service to governmental and industrial planning committees, to the councils of scientific and professional bodies, to editorial boards, international conferences, industrial consultancy; and to furthering the work of others. Honours coming thick included an honorary D.Sc. Strasbourg, distinguished medals and monetary awards, foreign membership of the National Academies in Sweden and the United States, and (with A. V. Hill) honorary founder-membership of the British Biophysical Society. His quick wit and breezy style made him a popular choice for memorial lectures such as the Procter, Mather, and Sylvanus Thompson.

Astbury's importance lies in the questions he asked and when—stimulus rather than detailed answer. He was an individualist, poet, shy and unsure rather than leader, artistic amateur not scientific professional, Elia his fellow, his strength and weakness the courage and zest the egoisms of a boy, and 'ware the colleague who had to "be of no school and have no master". He brought his findings to market in the green ear, but would not clear the weeds nor suffer the system and technique necessary for the harvest. Inevitably the protein-structural breakthrough was lost, and it hurt. Yet at bottom he had the humility of giants, kindly to failure and to youth, and one warmed to the Croonian and Harvey lecturer who obediently yielded the pavement to a youthful fellow-dreamer chugging along his imaginary track. If he relished the quip 'physicists and stamp-collectors' his view of biological research was latterly more akin to Hinshelwood's than to Rutherford's.

> "I have ventured,
> Like little wanton boys that swim on bladders,
> This many summers in a sea of glory,
> But far beyond my depth."

He would rest content with the simple tribute 'salute to adventurers'. Married in 1922, he leaves a widow, son and daughter. I. MacArthur

When I joined Sir William Bragg's team in the Department of Physics at University College, London, in 1922, W. T. (Bill) Astbury was decidedly the most colourful personality there. He took me under his wing and helped me in every possible way. I think it was partly his natural kindness and partly the fact that his intense happiness in his recent marriage to a lovely young Irish girl made him feel fatherly towards all young people. He was so full of enthusiasm for his work that none of us could feel it to be drudgery, even though it entailed sitting for hours on end with one eye glued to a microscope taking readings of the movements of a gold leaf. He was so delightfully pleased with his own achievements, not only then but throughout his life, that it was impossible not to rejoice with him; and he did achieve miracles with what would have seemed to most people almost intractable problems. Any discussion in which he took part, whether it was about crystal symmetry or about politics, became at once a matter of the greatest interest; any game that he played (and especially our lunch-hour international table tennis tournaments at the Royal Institution) became the more lively because he took part: the normal game was often too slow for him, and he would initiate some twist (five marks extra for hitting the matchbox off the table) to make it more fun. I count myself fortunate to have been one of his friends and colleagues.

Kathleen Lonsdale

Mr. W. V. Lewis

William Vaughan Lewis, lecturer in geography at Cambridge and Fellow of Trinity College, was killed in a motor accident at De Witt, Iowa, on June 8. His work gave him a high standing among geographers in Britain and abroad. With his exceptional eloquence and vitality, he was a born teacher. He was a good friend and had an enduring influence on the lives of many people. His early death comes as a great shock.

Vaughan Lewis was born at Pontypridd in 1907, and was educated at Pontypridd County School. He went up to Gonville and Caius in 1926 and so began a life-long connexion with Cambridge. He read Part I of the Mathematical Tripos, then turned to geography, finding his enduring interest in physiography. After completing the Tripos in 1929 he remained, first as a student, and then as a University demonstrator. He became a lecturer in 1945, when 'freezing' of University appointments ended. In 1949, to his great pleasure, he was elected a Fellow of Trinity College.

Vaughan Lewis's research career began when Prof. (then Mr.) Steers took him to Scolt Head Island. He was intrigued immediately with problems of coastal deposition and morphology, turning his own attention to Dungeness. He was engaged mainly with coastal research, until in 1936 he visited Iceland and became a confirmed glaciologist. While this was the field of his greatest influence, he typically enlarged, rather than changed, his interests, later doing much research on Chesil Beach, the results of which remain to be published. He had also a secondary interest in hydrology.

His glaciological work, carried out mainly in Norway and Switzerland, was concerned particularly with aspects of the structure, flow and erosive influence of cirque and valley glaciers. Apart from his published contributions to glaciology, such as his lively exchanges on the cirque problem with D. W. Johnson, it should be recorded that he was personally responsible for making physicists interested in field-work on glaciology. He played a leading part in the affairs of the British Glaciological Society, which has much enhanced latterly the active development of glaciology in Britain and elsewhere. Vaughan Lewis initiated two intensive research projects in Norway. The results of the earlier investigation of cirque glaciers were published in a research memoir of the Royal Geographical Society, of which he was the editor. His personal interests in the Austerdalsbreen Valley glacier project are recorded in a recent joint paper in the *Glaciological Journal.* These investigations depended on the co-operation of numbers of workers in different fields, and on the active support of generations of Cambridge undergraduates and research students. Vaughan Lewis again and again caught the real interest of undergraduates and, naturally, gathered around him eager groups of volunteers for field-work. The range and vividness of his ideas were such that he had a catalytic effect on the work of others. He was always generous, and would continue to encourage and assist those whom he had inspired to undertake some investigation. He will be sadly missed in many places. Jean M. Grove

Mr. Geoffrey Parr

With the death of Geoffrey Parr on May 30 at the comparatively early age of sixty-one, a colourful and popular figure leaves the scientific world. Parr received his formal education as an electrical engineer at the Finsbury Technical College, and, after working for the Admiralty during the latter part of the First World War, became a lecturer and demonstrator at the City and Guilds Technical College. In 1926 he joined the Research Department of the Edison Swan Electric Co., Ltd., where the cathode-ray tube was undergoing some of its early developments. Then in 1932 he took charge of the same Company's Technical Service Department.

His real *métier* and flair, however, appeared to lie in the communication of knowledge—writing, publicizing, lecturing, editing and publishing.

In the middle 'thirties he published his first book, *The Cathode-Ray Tube and Its Applications*, which has since gone into many editions and become a standard work.

In 1941, Parr became the first editor of *Electronic Engineering* and did much to nurture that paper through its early phases and war-time difficulties. In 1948 he joined Messrs. Chapman and Hall, Ltd., as technical director, and remained in that appointment until his death, being responsible for the very considerable output of scientific books from this well-known house.

Recently, Parr wrote and published, in collaboration with Mr. J. Godfrey, *The Technical Writer*, a work which filled a much-felt void and should long remain an authentic guide to writing standards among scientific authors.

Apart from his professional work, Geoffrey Parr's 'side' activities were legion and these helped to absorb his boundless energy and enthusiasm. One of these was his association with Dr. Grey Walter in the development of the electro-encephalograph, for which Parr helped in the design and construction of the electronics and amplifiers, the whole forming the basis of a joint paper to the Institution of Electrical Engineers, entitled "Amplifying and Recording Techniques in Electro-biology" (*J. Inst. Elec. Eng.*, 90, 3; 1944).

He also lectured frequently to technical colleges and societies throughout the country, usually on some aspect of television. Parr interested himself in many scientific societies and helped in the practical management of several of them. Among these, and in particular, was the Television Society of which Parr had been a Fellow for nearly thirty years, and to which he devoted so much paternal care and devotion. Becoming honorary lecture secretary in 1936, honorary editor of the *Journal* in 1944 and honorary secretary in 1945, he gave unstintingly his free time and attention before, during and since the War years. In fact, he had only retired from the office of honorary secretary a fortnight before his death. He helped the Society survive the War and then grow into its present stature, and, to a large extent, he personally fostered all the important aspects of its development.

Geoffrey had a host of friends in the world of television, in technical publishing and journalism, and wherever men of science gathered; for his gaiety, informality and humanity hundreds will remember him gratefully and affectionately.

T. H. BRIDGEWATER

NEWS and VIEWS

Pure Mathematics at Aberystwyth :
Prof. V. C. Morton

PROF. V. C. MORTON retires in September from the chair of pure mathematics at Aberystwyth after thirty-eight years on the staff of the University College of Wales. Educated at King Edward VII School, Sheffield, and Merton College, Oxford, of which he was a scholar, he served in the Royal Corps of Signals during 1916–19. On his return he became Junior and Senior Mathematical Scholar of the University of Oxford. He lectured for a year at Brighton Technical College and in 1923 was appointed lecturer at Aberystwyth. He became independent lecturer and head of the Pure Mathematics Department in 1926 and professor in 1933. He investigated various geometrical configurations, his best-known work being contained in a series of papers on the cubic surface. Dean of the Faculty of Arts, twice dean of that of Science and vice-principal, he has served the College and the University of Wales in many capacities, most notably as acting-principal of the College in 1957–58. A gifted teacher and a stimulating lecturer, wise in counsel and disinterested in judgment, his integrity and magnanimity are an inspiration to his students and colleagues alike.

Prof. W. B. Pennington

DR. W. B. PENNINGTON, who has been appointed to succeed Prof. Morton, is thirty-eight years of age. He had a distinguished career in Cambridge culminating, after interruptions by war service in the R.N.V.R. (1943–46) and two years at Harvard University (1950–52), in a Research Fellowship at Jesus. Since 1953 he has been reader in mathematics at Westfield College, University of London. Dr. Pennington is well known to British mathematicians, not only for his contributions to the analytical theory of numbers, but also for his devoted activities in the service of the London Mathematical Society as member of Council, vice-president and *Journal* editor. With his forward-looking attitude to mathematics and the catholic range of his interests, extending to problems of mathematical teaching and administration no less than of research, Dr. Pennington has not stood aloof from the heart-searchings prevalent among mathematicians to-day, and his new appointment will enhance his opportunities for an effective part in the great debate. With his departure to Wales, Westfield College loses an able mathematician, a delightful colleague, an opening batsman and an accomplished baritone.

Physical Chemistry in Trinity College, Dublin:
Prof. D. C. Pepper

DR. DAVID CHARLES PEPPER has been appointed to the newly established chair of physical chemistry in Trinity College, Dublin. Prof. Pepper, born in 1917, was educated at Ushaw College, Durham, Bradford Technical College, from which he took the London degree of B.Sc., and Jesus College, Cambridge. Later, he was awarded the Cambridge degree of Ph.D. for work in the Department of Colloid Science in Cambridge. He was appointed assistant lecturer in Trinity College, Dublin, in 1945, and Fellow in 1951. He has been reader in physical chemistry since 1955, and has been a member of the Royal Irish Academy since 1953. Prof. Pepper's research career commenced with Sir Eric Rideal, with whom he worked on a variety of war-time topics, sponsored by the Scientific Advisory Council of the Ministry of Supply. These researches were concerned

—among others—with interactions between phenols and amine monolayers, catalytic oxidation of ethylene, the plastic and vinoelastic behaviour of solid–liquid dispersions and polymer gels, and the kinetics and mechanism of polymerization reactions. The last-named topic has formed the basis of Prof. Pepper's interests in Trinity College, Dublin, most of his work being in the field of polymer solutions or in studies of the kinetics and mechanism of cationic polymerization. His research school has revealed some of the special characteristics of these reactions, notably the effect of solvents both through their dielectric behaviour and as co-catalysts. His work has focused attention on the considerable kinetic differences between these ionic polymerizations and free-radical polymerizations. It is true to say that contemporary theory in this field is largely based on ideas developed in Prof. Pepper's research group.

U.S. National Bureau of Standards: New Appointments:

Mr. Martin T. Decker

Mr. Martin T. Decker has been appointed chief of the Tropospheric Measurements Section of the National Bureau of Standards Laboratories at Boulder (Colorado). Mr. Decker joined the Bureau staff in 1949, his early work being in the area of tropospheric forward scatter of radio waves. More recently his research has been primarily in air-to-ground communications, including air navigation and airborne television studies, especially the prediction of reliability. He has also made studies of the obstructing effects of various materials on radio waves at VHF, UHF and SHF. Born in Byron, Nebraska, in 1927, Mr. Decker received his B.S. degree in electrical engineering from the University of Nebraska in 1950. He has continued his engineering studies at the University of Colorado.

Mr. John L. Hague

Mr. John L. Hague, a national authority in the field of analytical chemistry, has been appointed chief of the Standard Reference Materials Section. Mr. Hague had been acting chief of the predecessor section, Analytical Chemistry, since March 1960. The Standard Reference Materials Section will play an important part in the Bureau's standard materials programme. In this programme, the Bureau makes available for distribution to science and industry more than 550 different standards of metals, ores, ceramics, chemicals, hydrocarbons, and more recently added radioactive materials, uranium isotopes, lithium ores, aluminium refractories, and phosphor materials. Standard materials are used to check, evaluate and standardize methods of analysis and analytical techniques and substances, and to develop new and improved methods and instruments. Mr. Hague joined the Bureau staff in 1930 as a laboratory apprentice. In 1932 he transferred to the Norfolk Shipyard and three years later was in charge of the Foundry Control Laboratory for ferrous and non-ferrous alloys. He returned to the National Bureau of Standards in 1935 and in 1951 became assistant chief of the Analytical Chemistry Section. Born in Kansas City, Missouri, in 1912, Mr. Hague received his B.S. degree in chemistry in 1938 from George Washington University and has done graduate work there. In 1958, Mr. Hague received the Department of Commerce Meritorious Service Award "for outstanding original contributions to methods of analysis necessary for controlling the production of complex metal alloys".

Mr. John K. Taylor

Dr. John K. Taylor, research chemist, whose entire 32-year professional career has been with the National Bureau of Standards, has been appointed chief of the Applied Analytical Research Section of the Bureau's Analytical and Inorganic Chemistry Division. The Applied Analytical Research Section is concerned with the development and application of methods for the analysis and characterization of solids, liquids and gases. Both classical and instrumental methods of analysis are employed, using both macro- and micro-techniques. The Section also provides analytical consultation services and assistance for other Bureau programmes. A major part of Dr. Taylor's work at the National Bureau of Standards has been concerned with the application of physical methods to chemical analysis, including the polarographic method and the limitations of voltammetric processes. Recently he has conducted research in high-precision coulometric methods of analysis. Dr. Taylor has written numerous papers on these subjects, and in 1960 was awarded the Department of Commerce Silver Medal in "recognition of his contributions to accurate electrochemical methods of analysis". Other areas of research interest for Dr. Taylor have included refractometry methods for separation of isotopes, and a programme for providing a series of uranium isotope standards. This last has consisted of high-precision analysis of uranium compounds and the blending of highly purified isotopic species for mass spectrographic analysis. Born in Mt. Ranier, Maryland, in 1912, Dr. Taylor received his B.S. in chemistry from George Washington University in 1934. He was awarded his M.S. and Ph.D. from the University of Maryland in 1938 and 1941, respectively. Throughout his professional life, Dr. Taylor has been an active supporter of science education. He is a member and past chairman of the Joint Board on Science Education of the Washington Academy of Sciences and is editor of *The Reporter*, a news-letter for science and mathematics teachers.

Public Investment and Export

Under the title "Public Investment and Export" an article by Sir Walter Benton Jones, Bart., which originally appeared in the *Times Review of Industry*, March 1961, has been, with the addition of some figures for public spending 1950–59, issued as a pamphlet (Pp. 7. Grantham: Sir Walter Benton Jones, Irnham Hall, 1961). Sir Walter asks the leading question: Has Britain reached a level of public spending which may jeopardize her power to compete in the expanding export markets of the world, which may soon become more competitive than at any time in history? Pointing out that public spending has risen from £3,692 million in 1950 to £5,099 million in 1955 and £6,237 million in 1959, whereas exports increased by 33 per cent in the first period and only 16 per cent in the second, compared with increases of 49 per cent and 20 per cent, respectively, in world exports, 52 per cent and 13 per cent, respectively, for the United States, and 21 per cent and 33 per cent for West Germany, he suggests that the high level of our public spending may be handicapping our exports. Sir Walter suggests that since Parliament ultimately fixes and controls public expenditure, Parliament should be concerned to regulate the level of public expenditure by public income after due regard to possible effects of taxation on production and export, and that what is primarily needed to stimulate export is a considerable easing of the burden of taxation. He does not suggest any particular reductions in expenditure and admits that much expenditure is desirable or essential, but the argument is one with implications which the scientist might be wise to consider.

Nutrition Society of Canada

At the fourth annual meeting of the Nutrition Society of Canada, held at the Ontario Agricultural College, Guelph, on May 30, the following officers were elected: *President*, Dr. E. H. Bensley, Montreal; *Vice-President*, Dr. R. H. Common, Macdonald College; *Treasurer*, Dr. J. A. Campbell, Ottawa; *Secretary*, Prof. E. V. Evans, Guelph; *Councillors*, Dr. J. M. Bell (1964), Saskatoon, Dr. L. P. Dugal (1963), Ottawa, and Dr. W. W. Hawkins (1962), Halifax. A feature of the annual dinner of the Society was the announcement of the winner of the second Borden Award of the Nutrition Society of Canada for research in nutrition. This year's winner, Dr. Donald Fraser, of the Research Institute, Hospital for Sick Children, Toronto, Ontario, was cited for his work on vitamin D-refractory rickets in children and on varied aspects of calcium and phosphorus metabolism. The special speaker at the dinner was Dr. Ross A. Chapman, assistant director, Scientific Services, Food and Drug Directorate, Ottawa, whose topic was "Research in the Food and Drug Directorate". The one-day Society programme included a session of short research papers and a symposium on "Current Problems in Nutrition".

New Thinking in School Mathematics

A revision of the school curriculum in mathematics is needed for two main reasons. First, the gap between school mathematics and new mathematics is increasing, though it is more than ever important that the average intelligent citizen should understand that mathematics is the true foundation of our technological society. Secondly, the shortage of mathematics teachers might be partially remedied by ensuring that no time is wasted by teaching valueless or outmoded material. The Organization for European Economic Co-operation arranged a survey and a seminar at Royaumont attended by about fifty representatives from Europe and North America. A report, edited by Howard Fehr, is now available (Pp. 246. Paris: Organization for European Economic Co-operation, 1961. 10 N.F.; 15*s*.; 2.50 dollars; 8.50 D.M.). Part 1 summarizes the proceedings of the seminar. There was a general demand for a reduction in old-fashioned geometry, the inclusion of modern ideas in algebra, possibly with an abstract basis, and the introduction of probability and statistics. The implementation of such a programme would require new text-books and equipment, revised courses for teacher-training, and the re-education of serving teachers. Part 2 gives the results of the survey of present practices and trends, with much valuable information concisely presented. The volume should be studied carefully by all teachers of mathematics; even if they quail at some of the ultra-radical suggestions, they will appreciate the insistence on pattern and structure as the essence of mathematics.

Coryndon Memorial Museum, Nairobi

The annual report of the Coryndon Memorial Museum for 1959 is, as usual, a record of much progressive work. This included the establishment of a Snake Park and Snake Study Centre surrounded by a Botanical Garden, to which there was immediate popular approval (Pp. 24+1 plate. Nairobi: Museums Trustees of Kenya and Coryndon Memorial Museum, 1961. 1*s*.). All Departments of the Museum are in urgent need of cabinets for storage, especially in view of the almost indescribable dust problem in dry, windy weather. A number of new exhibits was completed. These include a habitat group depicting the swordfish, two giant fossil human milk teeth from the Olduvai Gorge and a leopard habitat group.

Western Australian Museum

The annual report of the Western Australian Museum for the year ended June 30, 1960, records the separation as from May 27, 1960, of the Museum and the Art Gallery. The Trustees of the combined institution have been replaced by two Boards of five members each. Consequent on this separation the Art Gallery moved out of the present James Street wing. Appropriately, the report includes an illustrated short historical sketch of the Museum, together with a comprehensive statement regarding future policy in relation to the various Departments. An account is also given of the major expeditions undertaken during the year, and these include one to investigate the fauna and flora of the Bernier and Dorre Islands in Shark Bay, another to Northwest Cape, and assistance given to the Bernice P. Bishop Museum of Hawaii when it had a mollusc-hunting expedition in Western Australia. The practice of including a short summary of papers published by members of the staff is useful and worthy of commendation.

Treatment of Varicose Veins

Varicose veins of the lower extremities are a frequent and highly disabling condition. Their surgical management has undergone a great number of variations since varicosities were treated by puncturing and drainage in the Hippocratic era. The exact ætiology of varicose veins still remains obscure; the disease may tend to be progressive, and morbidity causes economic strain on the patient and the community. Yutaka Kato and Robert A. Nabatoff, of the Department of Surgery, the Mount Sinai Hospital, New York City, N.Y., have carried out complete stripping of varicose veins of the lower extremities under local anæsthesia (*Yokohama Med. Bull.*, 11, No. 6; December 1960). This permits, almost immediately, post-operative ambulation and minimizes thrombo-embolic phenomena. The number of incisions depends on the number of incompetent perforator veins. All incompetent perforators are accurately mapped out pre-operatively, and all are ligated flush with the deep veins prior to the stripping procedure. Since all the veins communicating with the diseased great saphenous system and all 'blow-outs' in other locations are interrupted, and since the remaining varicose vein segments are stripped out, very few, if any, injections of sclerosing solution are necessary following operation.

The American Philosophical Society

Year Book 1960 of the American Philosophical Society contains, besides the lists of present and former officers of the Society and of former and present members, the charter and laws of the Society, and a brief history of the Society by E. G. Conklin (Pp. 786. Philadelphia: American Philosophical Society, 1961). The largest of the reports of committees is that of the Committee on Research, which includes lists of the 170 grants totalling 165,609 dollars made in 1960 from the Penrose Fund and of the 53 grants, totalling 53,473 dollars, made from the Johnson Fund. Four fellowships, totalling 27,400 dollars, were awarded from the Darland Fund. Reports from recipients of grants occupy almost 400 pages of the 416 of the Committee's report. Among the biographical memoirs included in the volume may be mentioned those on R. C. Andrews, W. H. W. Baade, N. L. Bowen, O. E. Buckley, A. L. Day, Sir Walter Wilson Grey, M. von Laue, L. Loeb, S. A. Mitchell and E. C. Tolman.

Cigarette Smoke Condensate

THE Tobacco Manufacturers' Standing Committee has published a second edition of its Research Paper No. 4, *Cigarette Smoke Condensate: Preparation and Routine Laboratory Estimation* (by H. R. Bentley and J. G. Burgan. London, 1961). This largely follows the first edition published in 1959, which it supersedes; but in the new edition the section referring to routine laboratory estimation of the yield of cigarette smoke condensate has been revised and extended. The standard method given in the first edition has been modified in the light of experience in order to improve the reproducibility of results. In particular, collection of smoke particulate matter by means of a 'Cambridge' filter followed by drying to constant weight is recommended for general use on grounds of simplicity, in preference to electrostatic precipitation, which has been found to have some disadvantages for quantitative work. Consideration is also given to the definition of realistic smoking conditions to be used with automatic smoking machines, and parameters, based on observations of smokers, of one puff of 2-sec. duration and 25-ml. vol./min., are recommended. These values are useful to have, for it would clearly be an advantage if some such agreed parameters were to be adopted in all laboratories in the United Kingdom in which cigarette smoke is being prepared and investigated.

Colour in Factories

COLOUR in industry is not merely a form of decoration or even a welfare measure. It has certain functions to perform and the factors important for success have been established. The latest report in the Factory Building Studies series, based on several years work on the use of colour in various types of building, is a concise guide for factory managements and their architects or colour consultants (Factory Buildings Studies No. 8. *Colouring in Factories*. Published for D.S.I.R. by H.M.S.O. Price 7*s*. 6*d*., postage 4*d*.). It has two sections, both containing coloured illustrations. The first section describes the basic properties and effects of colour, linking them with certain facts about human eyesight, to form general principles of colour design. The second section explains the practical application of these principles. It indicates stage by stage the way in which colour for each element of the interior becomes disciplined so that a picture is formed of the characteristics essential to good factory colouring. The examples are mainly for daylight, but there are notes on the special problems arising where lighting is wholly or partly artificial. As lighting and colouring are interrelated, this work is complementary to the earlier work (No. 2 in the series) on *The Lighting of Factories*.

The Content of Jobs

To the steadily growing number of broadsheets which are being produced to assist all who are concerned with the personnel function of management, the Institute of Personnel Management has now issued one called *Job Analysis*. Prepared by H. E. Roff and T. E. Watson, of Management Selection, Ltd., the broadsheet defines job analysis as "the scientific study of statements of all the facts about a job which reveal its content and all the modifying factors which surround it". Accepting that much of what passes for job analysis to-day is scarcely scientific, the authors show how a systematic approach to the analysis of a job can help all those who have to deal with human problems arising from the establishment of wage or salary scales, and the intricacies of selection, training and safety. Great difficulties confront industrial management in classifying one job against another and the method described in *Job Analysis* provides a useful *modus operandi*. For detailed information the reader must seek elsewhere, and the broadsheet contains a valuable bibliography which will help him to do this. *Job Analysis* is obtainable from the Institute of Personnel Management, Management House, 80 Fetter Lane, London, E.C.4, price 7*s*. 6*d*.

European Organic Geochemistry Group

AT a recent meeting of members of various European geochemistry groups it was proposed that a European section of the Organic Geochemistry Group of the Geochemical Society should be formed. At present the Organic Geochemistry Group has 250 members, 45 of whom are resident in Europe. The Group held very successful meetings in Denver last autumn, and this year meetings are to be held in Cincinnati. As such, countries interested in such an organization include Italy, France, the United Kingdom, Germany and Holland. The possibility of a meeting in Milan during September 1962 is being considered. Persons interested in such an organization should write to Dr. G. D. Hobson, Department of Geology, Imperial College of Science and Technology, Prince Consort Road, London, S.W.7.

Oliver Memorial Fund Award for Blood Transfusion Work

THE Committee of the Oliver Memorial Fund intends making its fourteenth annual award of the value of £50 to a British subject whose original work, or services in connexion with blood transfusion, is considered to be a notable contribution to the research organization or donor aspect of this subject. The Committee will welcome applications and, in addition, communications directing its attention to suitable candidates. Applications should be submitted before September 30, and should be sent to the honorary secretary, Mrs. F. E. Bedborough, 105 New Park Avenue, London, N.13.

Australian Post-Doctoral Fellowships in Protein Chemistry

THE Division of Protein Chemistry of the Commonwealth Scientific and Industrial Research Organization, Australia, is offering a number of post-doctoral fellowships. The Division has been engaged on a comprehensive research programme on protein structure and chemistry for the past twelve years covering chemical, physicochemical, biophysical and histological studies. The Division is well equipped for work in these fields and the applicant will be able to work with either fibrous or globular proteins. The fellowships have a three-year tenure and provide fares for the Fellows and their families to and from Australia. Salaries of up to £A2,720, depending on experience, are offered. Further information can be obtained from C. Garrow, Division of Protein Chemistry, C.S.I.R.O., Wool Research Laboratories, 343 Royal Parade, Parkville, N.2, Victoria.

Ramsay Memorial Fellowships

The Ramsay Memorial Fellowships Trustees have made the following awards of new fellowships in chemistry for the year 1961–62: a general fellowship to Mr. M. J. How at the University of Birmingham ; a Japanese fellowship to Dr. H. Suginome at the University of Cambridge; a New Zealand fellowship to Mr. B. A. Grigor at the University of Leicester; a Spanish fellowship to Mr. Fernan Alonso Matthias at the University of Cambridge; United States fellowships to Dr. K. D. Carlson at the University of Oxford and Dr. D. W. Setser at the University of Cambridge. The Trustees have renewed the following fellowships for the same year to: Mr. A. Bewick (general fellowship) at the University of Durham; Dr. D. G. Watson (Glasgow fellowship) at the University of Cambridge; Mr. H. Krabbendam (Netherlands fellowship) at the University of Edinburgh; Mr. G. A. Rodley (New Zealand fellowship) at University College, London; and Dr. Maria Covadonga Rodriguez (Spanish fellowship) at the University of Oxford.

Statistical Quality Control and Acceptance Sampling

The College of Advanced Technology, Birmingham, is organizing a full-time course of three weeks duration on "Statistical Quality Control and Acceptance Sampling", commencing September 11. The course is primarily intended as an introduction to the subject. Nevertheless, it provides the basic training necessary for quality control engineers. The first fortnight will be spent in covering the general principles and procedures of quality control. The final week will be devoted to lectures by specialists from industry, and to visiting the works of firms using quality control, where members of the course will be able to see the practical application of quality control methods, and discuss the techniques and associated problems. Further information can be obtained from the Bursar, College of Advanced Technology, Gosta Green, Birmingham 4.

Food Science Conference

The new Food Research Laboratories for the Commonwealth Scientific and Industrial Research Organization, Australia, are being opened at North Ryde, near Sydney, on September 18, and, to mark the occasion, a conference on "Food Science" will be held there during September 19–22. The conference will take the form of three symposia: "Chemical Aspects of Food Processing"; "Factors affecting Meat Quality"; "Food Preservation and the Organization of Plant and Animal Tissues". Further information can be obtained from the Chief, Division of Food Preservation, C.S.I.R.O., Private Bag, Homebush Post Office, N.S.W., Australia.

University News : Birmingham

The following appointments have been announced: Dr. L. Riddiford, senior staff Fellow in nuclear physics, to be senior lecturer in the Department of Physics; G. Martelli, staff Fellow in nuclear physics, to be lecturer in the Department of Physics; Dr. S. Swierszczewski, to be research Fellow in nuclear physics in the Department of Physics; Dr. J. H. Broadhurst, to be senior research associate, and D. E. Kidd, to be research associate, in nuclear physics in the Department of Physics; Dr. C. A. Barson and Dr. A. E. Pedler, to be senior research Fellows in the Department of Chemistry; R. J. Heitzmann, to be research Fellow in the Department of Chemistry; R. G. Bird, to be lecturer in the Department of Civil Engineering; B. K. Gazey, to be research Fellow in the Department of Electrical Engineering; Dr. B. Henderson, to be research Fellow in the Department of Physical Metallurgy; G. R. Ogram and B. Walker, to be research Fellows in the Department of Industrial Metallurgy; Dr. A. T. Kolnai, to be Lloyd-Muirhead Fellow in social philosophy in the Department of Philosophy, for one year; J. R. Turcan, staff tutor in the Institute of Engineering Production, to be research Fellow in the Department of Engineering Production; Dr. B. J. Key, to be lecturer in neuropharmacology in the Department of Experimental Psychiatry; Dr. R. R. Dils, to be lecturer in the Department of Medical Biochemistry and Pharmacology; D. Rimmer, to be lecturer in the Department of Economics.

Edinburgh

J. H. Turner has been appointed as lecturer in pathology. The following have been appointed Imperial Chemical Industries Research Fellows for a period of three years, with effect from October 1: Dr. I. Bihler (Hebrew University); Dr. J. Newham (Hull); C. McGreavy (Yale); Herman Wen-Geun Chew (Chicago); Dr. A. S. Milton (Oxford).

London

Dr. M. Gordon, senior lecturer in physical chemistry at the Imperial College of Science and Technology, has been appointed to the University readership in physical chemistry tenable at that College. The title of reader in demography in the University of London has been conferred on Mr. J. Hajnal, in respect of his post at the London School of Economics and Political Science.

Manchester

On an initiative jointly taken by Unilever Ltd. and the Department of Economics of the University, a Centre for Business Research is to be set up in Manchester. The Centre, which will be financed by money from industry, will, with the assistance of the co-operating firms, study some of the difficult problems of business decisions, and the ways in which economic, statistical and econometric knowledge can be used to help the decision-making of British business. Support has been guaranteed for an initial period of seven years, and it is hoped to appoint the first members of the full-time staff within a few months. The project will be directed by Prof. C. F. Carter, J. Johnston and B. R. Williams.

Sheffield

Dr. N. H. March, at present reader in theoretical physics, has been appointed to the newly created second chair of physics as from October 1.

The following new appointments have also been made: Dr. V. C. L. Hutson, to be lecturer in applied mathematics; J. W. Ross, to be junior research

Fellow in physics; Dr. I. Hawkes, to be lecturer in the Postgraduate School of Mining; Dr. C. J. Ball, to be lecturer in metallurgy; I. Livingstone, to be lecturer in economic statistics; P. E. Brown, to be senior lecturer in preventive medicine and public health; W. T. Baker, to be health physicist.

The Night Sky in August

NEW moon occurs on Aug. 11d. 10h. 36m. U.T. and full moon on Aug. 26d. 03h. 14m. The following conjunctions with the Moon take place: Aug. 5d. 17h., Aldebaran 0·3° S.; Aug. 7d. 18h., Venus 3° N.; Aug. 14d. 18h., Mars 2° S.; Aug. 23d. 15h., Saturn 3° S.; Aug. 23d. 23h., Jupiter 3° S. In addition to these conjunctions with the Moon, Venus is in conjunction with Pollux on Aug. 24d. 11h., Venus being 7° S. There will be an annular eclipse of the Sun on Aug. 11, invisible at Greenwich. There will be a partial eclipse of the Moon on Aug. 26, visible at Greenwich. The Moon enters penumbra at 0h. 36·1m., enters umbra at 1h. 34·9m., leaves umbra at 4h. 41·5m., and penumbra at 5h. 40·4m., the magnitude of the eclipse being 0·992. Moonset at Greenwich on Aug. 26 is at 5h. 11m. Mercury is too close to the Sun for observation. Venus is a morning star, rising at 1h. 05m., 1h. 15m., and 1h. 50m. on Aug. 1, 15 and 31, respectively. Its stellar magnitude on Aug. 15 is − 3·5; the visible portion of the apparent disk increases from 0·683 to 0·792 during the month and its distance from the Earth increases from 96 to 115 million miles. Mars is too close to the Sun for observation. Jupiter sets at 3h. 50m., 2h. 40 m. and 1h. 30m. at the beginning, middle and end of the month, respectively. It is near the border of Sagittarius and Capricornus; its stellar magnitude on Aug. 15 is − 2·3 and its distance from the Earth 385 million miles. Saturn sets at 3h. 20m., 2h. 15m. and 1h. 10m. on Aug. 1, 15 and 31, respectively. It is in Sagittarius; its stellar magnitude on Aug. 15 is + 0·4 and its distance from the Earth is 845 million miles. There are no occultations of stars brighter than magnitude 6 visible at Greenwich. The Perseid meteors are active during the first half of the month. Maximum activity occurs on Aug. 12, the radiant is at R.A. + 3h. 04m., Dec. + 58°, and conditions for observation are very favourable.

Announcements

DR. ARNO SIGVARD EKLUND, of Sweden, has been appointed director-general of the International Atomic Energy Agency, in succession to Mr. Sterling Cole, whose four-year term of office ends on November 30, 1961. Dr. Eklund was secretary-general of the second United Nations Geneva Conference on the Peaceful Uses of Atomic Energy in 1958, and is chairman of the international board of management of the Organization for European Economic Co-operation High-Temperature Reactor Project *Dragon* at Winfrith Heath, Dorset.

DR. MORTEN SIMONSEN, lecturer in immunology, University of Copenhagen, has been appointed director of research at the McIndoe Memorial Research Unit, Queen Victoria Hospital, East Grinstead, Sussex, which is devoted to the study of tissue transplantation and associated problems of wound healing.

MR. J. P. CATCHPOLE, of the Department of Chemical Engineering, University of Birmingham, has been awarded the student's prize of the Institution of Chemical Engineers, for his paper entitled "Frequency Response Techniques for the Study of Packed Bed Characteristics". This is the first award of this prize, which is open to student members of the Institution of at least six months standing at the time of presentation or publication of the paper.

ARTHUR GUINNESS SON AND CO., LTD., have established a scheme of awards of cash prizes totalling up to £500, to be called the Guinness Awards for Science Teachers in Training. The scheme is administered by *The Science Teacher*, the editorial director of which, Mr. Maurice Goldsmith, is chairman of the Guinness Awards Advisory Committee. The object of the scheme is to encourage students in teacher-training to develop and report on their own original contributions to the pedagogy of science in all its branches. The scheme will begin to operate as from September 1961. Further information can be obtained from the Information Office, Arthur Guinness Son and Co. (Park Royal), Ltd., Berk House, 8, Baker Street, London, W.1.

AN international congress of aviation and cosmonautical medicine is being held in Paris during September 26–30. Further information can be obtained from the secretariat, C.E.R.M.A., *5bis* avenue de la Porte de Sèvres, Paris, France.

THE Faraday Society has arranged a general discussion on "The Structure and Properties of Ionic Melts" which will be held in the Department of Inorganic and Physical Chemistry, University of Liverpool, during September 5–7. Further information is available from the Secretary, Faraday Society, 6 Gray's Inn Square, London, W.C.1.

THE sixth annual conference of the British Society for the Philosophy of Science is being held at St. Hugh's College, Oxford, during September 22–24. The following are included in the programme: explanation in psychology; learning machines; genetic coding and information theory; statements about the universe. Further information can be obtained from Dr. M. B. Hesse, Whipple Museum, Free School Lane, Cambridge.

THE First International Conference on Timber Engineering will be held in the University of Southampton during September 18–23. General problems of timber construction, structural timber joints, structures of particular interest, testing of timber structures, timber shell structures, constructional problems and economics and comparisons are the main subjects which will be discussed. Further information can be obtained from Dr. H. G. Allen, Department of Civil Engineering, University, Southampton.

A SERIES of postgraduate full-time courses is to be held in the Nuclear Studies Section of the Department of Chemistry and Biology, Liverpool College of Technology, during the 1961–62 session. These include a seven-months course in radiation safety and health physics, a number of two-week courses in radiation safety, radiobiology and radiochemistry, and a one-week course in radiation chemistry. Further information can be obtained from the Principal Lecturer and Organizer in charge of Nuclear Studies, Chemistry and Biology Department, College of Technology, Byrom Street, Liverpool 3.

HAZARDS OF THE ANIMAL HOUSE

THE Laboratory Animals Centre continued its series of annual symposia with a discussion on "Hazards of the Animal House" at the Royal College of Surgeons of England, London, on May 30. As a first discussion of this problem, the symposium was concerned with the general assessment of the situation, indicating the risks involved in handling animals suffering from natural and experimental infections and outlining the methods by which these risks might be reduced. Attention was also directed to hazards from sources other than pathogenic organisms, including risks involved in experiments with radioactive material, allergic reactions to experimental animals and traumatic risks due to careless handling of animals.

Since, perhaps, the greatest hazard of the animal house is that the worker should be unaware of the risks to which he is exposed, it is natural that many of the papers dealt with various agents which could be transmitted from animals to man. Early in the symposium, Mr. Bywater referred to the fact that, although the first case of infection of man with *B* virus from a monkey took place in the 1930's, it seemed that the risk had not been appreciated until comparatively recently. Rules for the conduct of animal houses, aimed at the protection of not only the scientific worker but also the animal house staffs themselves, have been drawn up in the past few years. Such rules are of obvious value in dealing also with dysentery and other intestinal conditions, which are transmissible from monkey to man. Dr. Sommerville listed the natural infections of laboratory rats and mice which are transmissible to man. Lymphocytic choriomeningitis has not been encountered frequently in man in Great Britain, although it appears to be fairly common in the United States, sometimes producing an influenza-like syndrome, at other times a biphasic illness with an aseptic meningitis. The encephalo-myocarditis virus of mice is also of reasonably frequent occurrence, but other viruses are rare. On the bacterial side, *Pasteurella septica*, although found both in rodents and in man, has not often been clearly demonstrated as having passed from one to the other. However, since it has caused fatal illness in man, it should be taken seriously. Leptospirosis is also of importance.

A second group of infections is caused by viruses and bacteria transmitted from mice or rats inoculated in the laboratory with diagnostic material or with stock viral or bacterial cultures. In this second group, infection is much more frequent than by viruses and bacteria naturally carried by the animals, but the laboratory worker is usually on the lookout for the agent concerned. The worker may not always be ready, however, to realize the ease with which infection may be transmitted by inhalation or ingestion of dust from cages contaminated with excreta or nasopharyngeal material from the rodents.

Mr. McNeil dealt with the more specialized topic of the hazards associated with farm animals. He emphasized the importance of selection of healthy animals for experimental work both by clinical examination and by application of tests such as tuberculin tests and agglutination tests for *Brucellosis*. A quarantine period on arrival is valuable, since it also allows parasitic conditions such as ringworm, lice or mange to be dealt with. Most of the conditions which affect farm animals are likely to be familiar to the staff engaged in handling these species. Careless post-mortem technique, though perhaps not strictly part of the animal house routine, was referred to as a source of infection in such conditions as anthrax and swine erysipelas. Mr. Hodgman dealt with the hazards encountered in dealing with dogs and cats. He considered that the risks from disease are not of great importance in Great Britain, the main hazard being the traumatic one from bites and scratches. Conditions affecting dogs and cats and transmissible to man are more likely to be apparent in owners of pets than in laboratory workers.

Mr. Garratt spoke of the hazards associated with the use of radioactive substances in animal experiments. His main conclusion was that health hazards to personnel from external irradiations are usually negligible and those resulting from internal irradiation after ingestion or inhalation of radioisotopes could be prevented by careful handling. Careful disposal of waste was of great importance. In general, the attitude of the worker with radioactive substances in animal experiments might be summarized by the maxim: "Take care of your experiment and your health will take care of itself". Other specialized problems were dealt with by Dr. Cooper on the handling of large-scale experiments with polio virus, mainly from the laboratory point of view, and by Dr. Rees on precautions against tuberculous infection in the animal house and laboratory. Both these speakers were concerned mainly with the techniques which would reduce risks to the workers with the agents concerned and both referred to the advisability of vaccination of staff. Surgeon Commander Darlow dealt with the general topic of the provision of clean air as a factor in preventing the spread of infection in the animal house. He showed how considerable reduction in the number of airborne organisms could be effected by suitable air filtration. The use of ultra-violet light was recommended as the simplest method for killing airborne organisms. Mr. Porter dealt with the traumatic hazards not only from the animals themselves but also from damaged or incorrectly designed equipment. From the economic point of view, the minor accidents of the animal house (graphically illustrated by Mr. Porter) interfere considerably with efficient working. Cracked water bottles, damaged cages and bins all provide sharp edges on which fingers and hands can readily be cut or scraped, with consequent loss in working time.

Summarizing the discussion, the chairman, Dr. J. B. Brooksby, said that the first point that had been made was the necessity for awareness among research workers of the risks involved in handling any species. A remark had been made from the floor that any worker about to begin experiments with monkeys would do well to consult some of the laboratories concerned in handling the species in large numbers. Similarly, any worker dealing with any new or exotic species should try to obtain all possible information before beginning his experimental work. This symposium might, however, serve as an initial stage in the documentation of the various agents which should be considered as hazardous in the animal house. An important point seemed to be that the various risks were kept in their true perspective. Thus, *B* virus infection from the bite of an apparently healthy monkey was obviously far more serious than the unpleasant, but relatively trivial, infection by ringworm from a domestic animal. Just as the severity of infection varied from agent to agent, so the chances of infection from animal to man would vary, and the proper assessment of the dangers involved in any particular type of work would take into account these factors.

The action to be taken to avoid the hazards of the animal house would obviously relate to the degree of risk. Commander Darlow's paper indicated the way to the ultimate degree of protection possible, by designing a special building with air-filtration and all other apparatus necessary for restriction of airborne micro-organisms. Various practical steps could, however, be taken to reduce risks in accommodation already available. Several speakers emphasized the need for taking only healthy animals into the animal house. The value of tuberculin testing in monkeys was discussed, and there was some divergence of opinion as to its value. Restriction of risk in operative procedures could often be achieved by the use of hoods, anti-splash guards and other equipment of this sort. The point had also been made that spread from an animal often occurred after the object of the experiment had been achieved and there was no case, for example, for keeping tuberculous guinea pigs after the primary lesion had developed; they could be destroyed before caseation supervened. Another problem which was of great importance was staff discipline, particularly where large numbers of animals were being handled and much of the work was necessarily undertaken by staff recruited untrained. Training took place after appointment, when new staff members were undertaking potentially dangerous work. Attention to proper sterilization techniques and to the disposal of bedding and dirty equipment was most important. The use of proper equipment in a good state of repair was also a prime necessity for the avoidance of undue risks.

It will be realized that many of the steps that must be taken to control hazards are also those which would be taken in any animal house dealing with infective agents, in order to prevent cross-infection among the animals themselves, and the instruction of workers in the health hazard may help to achieve the discipline which will, in turn, prevent both the health hazard and the hazard to the experiment itself.

USE OF ANIMAL CELL, TISSUE AND ORGAN CULTURES IN RADIOBIOLOGY

FOR nearly fifty years the tissue culture method has proved a valuable experimental tool for radiation studies. By isolating a group of cells outside the body the effect on blood- and nerve-supply and the reaction of the organism as a whole are eliminated and the direct effects of radiation can be accurately assessed. The establishment of clone cultures and the introduction of chemically defined media in the past decade have brought a further simplification and standardization of experimental conditions which make it possible to obtain precise quantitative data. At a symposium convened by the New York Academy of Sciences in February 1961, the effects of ionizing radiations on cell structure and differentiation, on mitosis and growth of cells in tissues grown *in vitro* were reported and correlated with changes in synthesis of deoxyribonucleic acid (DNA); the influence of oxygen tension, sensitizing and protective agents on radiation action was outlined, and variations in radiosensitivity discussed.

L. J. Tolmach (St. Louis) and J. E. Fogh (New York), using HeLa *S*3 and *FL* amnion cells, reconfirmed the well-known fact that radiation affects cell division much more than cell growth. Cells unable to divide continue to increase in size, reaching a maximum 2–4 days following exposure.

Y. Onuki, A. Awa and C. M. Pomerat (Pasadena) investigated the effect of radiation on the chromosomes of leucocytes cultured from the human buffy coat. A dose of 400 r. increased the number of tetraploids by 7 per cent and the number of cells showing chromosomal damage by 50 per cent. F. E. Osgood (Portland) interpreted the effect of radiation on normal and malignant human hæmic cells *in vivo* and *in vitro* in terms of his α-cell–n-cell concept. The potentially dividing α-cells give rise, as a rule, to another α-cell and a differentiating n-cell. Doses of 10–400 r. immediately inhibit the division of α-cells while the number of fully differentiated and longer-lived n-cells remains, at first, unchanged. Their number begins to drop when the reduced α-cells fail to replace n-cells which have reached the end of their natural life-span. In this range of dosages, radiation did not seem to inhibit synthesis of DNA of α-cells as they continue to incorporate tritiated thymidine after their increase in number is stopped. Comparisons of hæmic cells as regards their radiosensitivity show that normal and malignant lymphocytes are the most sensitive cells though even in these cells there is a marked individual variation in sensitivity.

The great sensitivity of lymphocytes was also emphasized by Schrek and Trowell. R. Schrek (Hines, Ill.) examined the immediate and delayed effects of radiation on human and animal lymphocytes. A dose of 1,000 r. produced severe intranuclear vacuolization and death within 24 hr. following exposure, while 10 r. reduced the 10 per cent survival-time from 9·7 to 6·1 days. There was no difference in radiosensitivity of human lymphocytes from blood or lymph nodes, but lymphocytes from rats, guinea pigs and rabbits were slightly less sensitive than human lymphocytes. O. A. Trowell (Harwell) described the influence of various gas mixtures on the action of radiation on lymphocytes from rat mesenteric lymph nodes and stressed the importance of choosing the right effect and end-point for measurements. For example, by counting dead nuclei 5 hr. after exposure an oxygen sensitivity factor of 12 was found, while counts of surviving nuclei 24 hr. after irradiation gave a sensitivity factor of 2·7—a value which agrees well with most other biological materials. Trowell attributes his original result to a slowing down of pycnosis by oxygen.

Another aspect of the action of radiation which received much attention was the effect on synthesis of DNA as measured by the uptake of tritiated thymidine and its correlation with mitotic inhibition and cell death. H. Harrington (Cleveland), using *U*12 fibroblasts, reconfirmed the classic findings of Strangeways and Oakeley on the effects of radiation on cell division. A rapid drop in mitosis after 500 r. is followed 13 hr. later by re-appearance of cell division. Counts of thymidine-labelled mitotic figures suggested that there was no accumulation of cells in the *G*1 interphase period but a delay in the synthetic *S* and premitotic *G*2 period, using the terminology introduced by Howard and Pelc. Similar findings were reported by R. B. Painter (Columbus) and W. L. Hughes (Upton), who found no evidence that radiation influenced the rate at which HeLa *S*3 cells moved from the *G*1 to the *S* period. The small immediate inhibition of synthesis of DNA could not be correlated quantitatively with the lethal effect of radiation or was the position of the cells in the synthetic cycle related with the probability of their survival. The three authors agreed that in contrast to synthesis of DNA, synthesis of ribonucleic acid (RNA) was practically undisturbed, even after high doses of radiation.

J. E. Till (Toronto) observed a generalized dose-dependent prolongation of all three stages of the first synthetic cycle following exposure. However, the *G*1 and *S* periods were only slightly prolonged. The greatest effect was seen on cells which had completed synthesis of DNA and had moved to the *G*2 period, which was severely disrupted by radiation. Thus, the effects of radiation on synthesis of DNA seem to be the result, rather than the cause, of mitotic inhibition.

A. N. Stroud and A. M. Brues (Argonne, Ill.) gave an interesting example of differences in synthesis of DNA response in two strains of pig- and monkey-kidney cells. After exposure the monkey-kidney cells which normally have a low rate of thymidine incorporation showed an increase of 15–20 per cent more than that of the unirradiated controls, while the pig-kidney cells which normally have a high rate of incorporation show a striking decrease. P. F. Sanders, D. F. Petersen and W. L. Langham (Los Alamos) described methods for growing HeLa cell suspensions in the presence of tritiated thymidine and tritium water, for determining cell size and cell number and for measuring radioactivity. Beta radiation from tritium has a much greater inhibitory effect on proliferation when emitted from incorporated ^{3}H-thymidine in the nucleus than when merely present in water.

W. B. Looney (Baltimore) pointed out some limitations of labelled compounds in radiobiological studies. Erroneous interpretations may be made as a result of reduced synthesis of DNA unless differences in time-sequence of control and irradiated systems are taken into account. For example, the generation time of hepatocytes in regenerating rat liver is increased from 8 to 13 hr. after 3,000 r.; thus, the ratios of synthesis of DNA of irradiated and control specimens between 8 and 13 hr. would be the ratio of the activity in a second cycle of hepatocytes in the controls to that of the first cycle of irradiated hepatocytes.

T. R. Munro (Cambridge) described a technique which allows selected parts of single cells to be irradiated with α-particles and showed a film of irradiated chick fibroblasts. When the chromosomes were irradiated with a sufficient dose sticky bridges were seen at anaphase and the reconstruction of daughter nuclei inhibited. Neither of these effects was seen if the radiation was confined to the cytoplasm. He also described a method which allows single HeLa *S*3 cells and their progeny to be followed for a week. This technique should enable cell survival to be studied after localized radiation.

G. O. Gey (Baltimore) described a more elaborate analogous technique for studying population dynamics of lymphoblasts in culture. His apparatus photographed a number of accurately defined fields of cells at intervals of 15 min. and enabled the fates of large numbers of single cells to be studied.

H. B. Hewitt (London), using an *in vivo* bio-assay of mouse leukæmic cells, measured their response to radiation and its variation with different degrees of oxygenation. For whole-body exposure of mice breathing air or oxygen the dose producing the same survival curves of leukæmic cells was lower by a factor of 2·3 as compared with mice killed shortly before irradiation. On the other hand, survival curves for cells of a solid sarcoma were similar for living and recently killed mice and identical with the anoxic curve obtained for the leukæmic cells. He concluded that variations in radiosensitivity between different mouse tumours are due to differences in their oxygenation. J. R. Andrews and R. T. Berry (Bethesda), using the same technique, gave the survival curves of a different strain of mouse leukæmic cells which grow normally under anoxic conditions in the animal. The cells showed an oxygen factor similar to that found by Hewitt. They also reported preliminary results on the effect of dose fractionation and on sensitization by some pharmacological agents.

A. Goldfeder (New York), in an interesting paper, gave her results on electron-microscopic and biochemical studies of tumour mitochondria, and showed that variations in radiosensitivity of two types of mouse tumour cells could be correlated with differences in mitochondrial structure and metabolism.

R. Bases (New York) demonstrated the sensitizing action of actinomycin *D* and deuterium oxide in experiments in which Puck's single-cell technique was employed. A dose of 300 r. sterilized 5–10 times as many cells pretreated with actinomycin *D* than controls. Cells pretreated with deuterium oxide were also abnormally sensitive to radiation, an effect attributed to a presensitization by incorporation of the drug into the DNA of the cells.

D. E. Rounds (Pasadena) reported a protective effect of yeast RNA. RNA-treated cells of the Fernandes strain of amnion cells multiplied at a normal rate following radiation while untreated cultures showed immediate inhibition, but a minimum time of 8 hr. was necessary before protection could be seen. The magnitude of the protection varied considerably with different cell strains. A. Schleich (Heidelberg) reported her results on radioprotective properties of various compounds, among them histamine, thioctic acid, cysteine and cysteinamine, tested on whole-body irradiated mice, a strain of human malignant fibroblasts and solutions of thymine and DNA. The protection varied with the system tested but was consistent for all systems with cysteine and cysteinamine.

In contrast to the previous papers, which dealt mainly with the effects of radiation on established cell strains, J. G. Carlson, E. Borghese and I. Lasnitzki described the action of radiation on freshly explanted cultures of organized tissues, which retain their histological structure *in vitro*.

J. B. Carlson (Knoxville) pointed out the advantages of his grasshopper neuroblast technique for quantitative radiation studies. The large size of the neuroblasts, their position on the surface of the embryo, their constant number and fixed arrangement in relation to each other simplifies cell counts, facilitates their identification and allows radiation effects to be followed through several division cycles. A disadvantage of the method is the great sensitivity of cell division to changes in osmotic pressure.

As in vertebrate tissues, X-radiation produces a mitotic inhibition due to an arrest of cells in late prophase followed by mitotic recovery. Increasing the oxygen tension does not increase mitotic inhibition but reducing it diminishes the effect of radiation. Investigations of frequencies of chromosome aberrations induced by X-rays show a peak at middle prophase and anaphase.

E. Borghese (Rome) showed in a beautiful film the growth of mouse embryonic lung explanted by the organ culture technique and the effects of γ-rays on this tissue. In the controls, development and outgrowth of clear translucent bronchi could be observed. After exposure the explants became opaque, growth slowed down and finally stopped.

I. Lasnitzki (Cambridge) reported that irradiation can change the pattern of differentiation in organized tissues grown *in vitro*. Mouse vaginal explants grown by the organ culture technique form squamous epithelium with a superficial layer of keratin. Exposure to X-rays inhibits the squamous development and keratin formation both in normal- and œstrone-treated vaginas. This effect is unrelated to mitotic inhibition and closely resembles that seen after treatment with excess vitamin A. It also agrees well with results obtained in *in vivo* experiments.

The symposium reflected the present trend to measure the biological effects of radiation and showed the advantages tissue cultures offer for such work.

ILSE LASNITZKI

THE NATIONAL CHEMICAL LABORATORY

THE report of the National Chemical Laboratory, 1960*, comprises the report of the Steering Committee over the signature of Prof. C. E. H. Bawn, and the report of the Director, to which are appended details of membership of the sub-committees of the Steering Committee and of the staff of the Laboratory at December 31, 1960, and lists of publications and patents during the year and of Standard Samples of Organic Compounds.

On consideration of the Laboratory's research programme in greater detail, the Steering Committee agreed that the work of the Extraction of Metals Group should include fundamental work on the inorganic and physical chemistry of hydrometallurgy in addition to work for the Atomic Energy Authority on ores and minerals. While the Radioisotope Applications Unit, established at Harwell as an out-station of the Laboratory in 1957 and now at the Isotope Research Division of the Atomic Energy Research Establishment at Wantage, is regarded as contributing to the National Chemical Laboratory's mandate to cultivate instrumental techniques, the Steering Committee found no justification for the Department of Scientific and Industrial Research to undertake any work on the direct uses of high-activity sources of radiation.

Considering the building programme of the Laboratory in relation the future development of its research programme, the Steering Committee formed the opinion that, to cover the possible forward requirements, the present staff of 264 should be increased by about one-half in the next 5–7 years and doubled in the next 10–15 years. It anticipates that the need for Government research in the chemical field will inevitably grow with the continued expansion of the chemical industry, and to provide the buildings needed for a staff more than double the present complement it recommends that the Laboratory be moved to a larger site as near the present site as possible, in view of the close and important co-operation with the National Physical Laboratory. The site should be large enough not only to accommodate the buildings for the National Chemical Laboratory but also to provide in the long term for possible expansion there of other existing laboratories or for new laboratories. The Research Council has already agreed that the possibility of acquiring such a site should be explored.

Commenting on the problem of determining the best balance of effort in a national laboratory, the director, Dr. J. S. Anderson, defines the task of the National Chemical Laboratory as that of carrying out research in areas that are important but that cannot be studied so effectively by agencies less centrally placed. It should seek to place new developments on a firm basis of scientific understanding, to ensure that all its investigations enrich scientific knowledge, and to bring a deeply analytical approach to bear on those major problems of wide application, such as the prevention of corrosion, which fall within its scope. The present research programme is still being developed, and Dr. Anderson notes some material changes in the work of several research groups during the year. Work on the physicochemical properties of organic compounds has been converted into a much more comprehensive programme of chemical thermodynamics, though full effect cannot be given to the projected scheme until the new buildings are available. The Extraction of Metals Group, which hitherto has been working almost entirely in associations with, and at the request of, the Atomic Energy Authority, is now including in its programme some fundamental work on the more familiar metals of industry. Collaborative arrangements with the National Research Development Corporation for work on the development and application of ion-exchange membranes and of gold-selective ion-exchange resins was terminated, but some work in this field is being pursued at a more fundamental level. Work in the Inorganic Group on the extreme purification of semiconductor materials was also substantially reduced and effort transferred to applications for the substantial quantities of rare-earth elements that are becoming available.

* Department of Scientific and Industrial Research. *Report of the National Chemical Laboratory*, 1960 : *Report of the Steering Committee and Report of the Director of the National Chemical Laboratory for* 1960. Pp. iv+70+4 plates. (London: H.M. Stationery Office, 1961.) 4*s*. 6*d*. net.

A small research unit was set up to continue the Director's fundamental research on the chemistry of solids, and in this unit the study of physical processes and chemical reactions on absolutely clean metallic surfaces, using the field-emission microscope, has commenced. A research fellowship has been established and work started on the related and very powerful technique of ion microscopy, which is capable of imaging individual atoms on the metal surface. The Chemical Thermodynamics Group made a critical examination of existing data, and, with the assistance of the Association of British Chemical Manufacturers, this has led to a recommendation that, on the organic side, the Laboratory should commence work on the aliphatic compounds containing oxygen and continue its work on phenols. The study of the purification and physical properties of phenol, cresols and xylinols has been completed for publication; work continued on the precise determination of the critical temperatures of certain pure hydrocarbons and the ebulliometric apparatus for measuring vapour pressure has been re-designed and re-built. In the Non-metals Group, particular emphasis was placed on boron–nitrogen compounds, and the systematic study of the chemistry of borazole and its derivatives promises to provide polymers with greater thermal stability than is usually associated with a molecular skeleton of carbon–carbon bonds. Compounds of promise as pre-ignition suppressors for motor 'petrol' have been obtained. Work on ion exchange materials, particularly ion-exchanging membranes, has been narrowed to a thorough study of selectivity and its exploitation, and increased attention given to polymers with potentially applicable electrochemical and electrical properties in the form of reversible redox polymers and high nolecular weight materials likely to exhibit semiconduction.

The Extraction of Metals Group has developed a modified rotary-film disk contactor for the solvent extraction of metals direct from solutions containing appreciable quantities of solids in which solvent and pulp flow parallel to the planes of the disks, and each stage contains several disks. This has given excellent recoveries of uranium, with acceptable solvent losses, from sulphuric acid-leached ore pulps and sulphuric or nitric acid-leached uranium concentrates. Promising results were also obtained in extraction of uranium by heap leaching with acid, and in co-operation with the Warren Spring Laboratory, the extraction and concentration of beryllium from concentrates containing 2–4 per cent beryllium oxide, derived by flotation from low-grade ores, has also been studied. Examination of the solution chemistry of beryllium, mainly concerned with developing methods for the selective recovery of beryllium from sulphate leach liquors, showed the pronounced tendency of beryllium to form polynuclear species in both weakly acidic and alkaline solutions.

The Inorganic Group has given considerable attention to the extraction of the reducible elements, samarium, europium and ytterbium, by sodium amalgam, and has developed a continuous process for recovering these elements from concentrates. The possibilities of a new and rapid method of extracting aqueous solutions of lanthanons with tributyl phosphate are being examined and the purification of gallium and arsenic is being studied with the view of the preparation of gallium arsenide as a semiconductor. The Corrosion of Metals Group is seeking a better understanding of the basic physico-chemical factors which control corrosion and oxidation processes, and of which account must be taken in devising solutions to specific problems. Special attention has been given to the relative importance of the surface preparation of mild steel and the anions present in the solution in which the steel is immersed. In the study of corrosion in moving water, attention has been given to the chemical nature of the corrosive products. The very high initial corrosion-rate of mild steel in oxygenated dilute chloride solutions at 200° C. has been determined, and relations have been established between the rate of corrosion of mild steel in batch cultures and the hydrogenase activity of sulphate-reducing bacteria. Work is also in progress on the distribution in soils of different species of sulphate-reducing bacteria, as well as a pilot investigation of the corrosion of mild steel exposed at two sites on the River Thames.

THE NATIONAL RESEARCH DEVELOPMENT CORPORATION

In its eleventh year of life, the National Research Development Corporation * negotiated more licence and option agreements with United Kingdom and overseas firms than in any previous year. Eighty-one such agreements were completed (as against sixty-one in the previous year) and, by June 30, 1960, some 456 such agreements were in force. Royalties and other payments received under licence and option agreements amounted to £259,000 as against £182,000 in the previous year. About half these receipts derived from overseas business, that is, from direct payments made by manufacturers abroad, and from royalties on goods exported abroad by United Kingdom manufacturers.

The outright sale of patent rights is another, but exceptional, form of exploitation activity, and is a fluctuating source of income.

By the end of 1960 the Corporation had a portfolio of 1,066 United Kingdom and 2,042 overseas patents and patent applications for inventions, derived chiefly from publicly supported research in the Government research establishments, research councils and the universities. The portfolio is under constant change. Unprofitable patents are allowed to expire, others lapse at the end of their periods of grant, and new accessions are continually being included.

At the end of 1960, the Corporation was providing financial assistance for thirty-five development projects. During the year, the Corporation's expenditure on development amounted to £427,000, and with its subsidiaries it has entered into commitments for £739,000 for development purposes. Recoveries of development expenditure amounted to £52,000.

---

* *National Research Development Corporation Bulletin*, April 1961.

One project which was commenced in the year under review was the automatic process plant control. This is concerned with the development of electronic automatic control equipment suitable for plant and process control automation and, for example, for the control of power stations and chemical plants. It contemplates the development of a range of standard equipment which will permit electronic analogue and mixed analogue/digital computing techniques to be used for this purpose, the individual elements being capable of assembly in a variety of ways to enable control systems to be designed as required for any particular plant.

The work is being undertaken by an established firm in the electronic computing and control engineering fields, which is sharing the cost with the Corporation. The project is still in its early stages, but work has started on the design of circuit elements and components, and on the study of potential plant applications.

FŒTAL AND NEONATAL PHYSIOLOGY

ALTHOUGH there have been great reductions in infantile mortality within the present century, it is only now being realized how much can be done to reduce mortality before birth and in the first days after it. The application of fundamental physiological principles to the management of premature infants has become a study in its own right. These principles were recently examined in the *British Medical Bulletin**, the contributions varying from investigations of blood pressures in new-born babies, the acquirement of immunity and immunological tolerance, protein and amino-acid movements in the fœtus and new-born animal, transport mechanisms in the placenta and red cells, enzyme development, the newer aspects of placental histology, fœtal endocrinology, and the chemoreceptors and their function in the aortic-pulmonary body.

Among the more outstanding experimental work is a review by Dr. R. Deanesley of the present position in fœtal endocrinology. Experimental operations by Jost, Wells and their collaborators, on pregnant rabbits and rats, and on fœtuses *in utero*, have shown that in these animals the pituitary and testes become active before birth and play a decisive part in differentiation. Thyroid and adrenal development is controlled by the fœtal pituitary. The developing fœtus at certain stages can react to exogenous hormones which reach it directly or through the placenta. The fact that the endocrine glands are active in the fœtus carries no implication that their secretions can affect the maternal physiology.

In their review of the fœtal kidney, Miss Pauline Alexander and Dr. D. A. Nixon show that development of function in the metanephros is spread over a period of time—some activities appearing earlier than others.

The onset of glomerular filtration precedes tubular activity so that large volumes of urine may be passed into the amniotic or allantoic sacs from an early age. Subsequent appearance of tubular activities results first in the production of a hypotonic and, later, a hypertonic urine. The maximal osmolarity of the urine is low by adult standards because of the low excretion of solute. The renal capacity to acidify the urine is limited in the early stages, in part by the very low excretion of phosphate. The glomerular filtration-rate appears to be somewhat labile at first, and the factors leading to its stability in later life are not known. Ratios for the clearance of *p*-amino-hippurate: inulin suggest that the supply of blood to the kidney is low in fœtal life in comparison with that in the adult, and this may limit its functional capacity considerably.

The stage of metanephric development at which a fœtus of any particular species attains an independent existence will determine its initial renal problems.

Dr. Heather J. Shelley has investigated reserves of glycogen and their changes at birth and in anoxia. However, there is no reliable information on the glycogen reserves of the new-born human infants, but, by analogy with other species, they probably have a high concentration of liver glycogen and a fair amount of muscle glycogen. New-born babies have been known to withstand anoxia for up to 30 min. (Bullough, 1958), so it is likely that their cardiac glycogen concentration is also high. Since lactation is not established in man until 24–48 hr. after parturition, the new-born baby must be particularly dependent on its reserves; if its liver glycogen falls as rapidly as in other species it will be in a precarious metabolic state for several days. If kept warm, the new-born baby can survive for several days without food, but if exposed to cold it later dies of hypoglycæmia (Mann and Elliot, 1957), probably the result of an attempt to maintain its body temperature (Bruck, 1959). It is therefore possible that factors which reduce the glycogen content of the fœtus *in utero* or at birth may jeopardize the infant's chances of survival after birth, and future work must determine to what extent the deleterious effects of maternal nutrition, placental insufficiency and birth asphyxia may be the consequence of inadequate glycogen reserves.

The ability of young mammals to withstand a total lack of oxygen was considered by Dr. Joan Mott. She believes that the practical conclusion to be drawn from the present state of knowledge of the conditions under which anoxic survival is possible is that the carbohydrate stores, particularly of the heart, should be protected from dissipation. Re-synthesis of carbohydrate does occur, but may be limited by the rate of entry of glucose into the cell. Thus the factor of vital importance is the store of carbohydrate already available within the cardiac cells. Repeated episodes of anoxia or hypoxia are cumulatively as well as individually dangerous, and it is probable that, if the *p*H is not restored to normal level, a stage is reached at which glycolysis may be completely inhibited. Repeated anoxic episodes may also exhaust the liver glycogen and lead to hypoglycæmia, so that maintenance of the circulation might be insufficient to protect the brain from injury.

* *British Medical Bulletin*, 17, No. 2 (May 1961): Fœtal and Neonatal Physiology. Pp. 79–176 + 8 plates. (London: British Council, 1961.) 20*s*.

From the available evidence showing the reaction of the new-born animal to environmental temperatures, Dr. June Hill suggests that the metabolism of the new-born of a warm-blooded species often differs from that of the adult animal in two important respects: first, the new-born animal has a lower basic metabolic rate than is appropriate for its surface area; and secondly, per unit surface area, the new-born animal has a smaller maximal metabolic response to cold. Thus the heat production of the new-born animal, both minimal and maximal, is lower per unit surface area than that of the adult. The degree of immaturity at birth probably determines to what extent the metabolism of the new-born deviates from the adult pattern.

In addition, the new-born animal often has a coat of lower effective insulating power than that of its parent; this is partly because the new-born is smaller than the adult, and is partly a specific attribute of immaturity. This means that, per unit surface area at a given environmental temperature, the new-born animal loses heat much more readily than the adult.

These facts underlie, and go far to account for, the difficulties which many new-born animals experience in maintaining a stable internal body-temperature.

LIFE AND SCIENTIFIC WORK OF SIR JAMES HALL

THE Bruce-Preller Lecture of the Royal Society of Edinburgh was delivered on June 5 by Dr. V. A. Eyles, formerly of the Geological Survey of Great Britain, who took as his subject, "The Life and Scientific Work of Sir James Hall, Bart., F.R.S. (1761–1832), Second President of the Royal Society of Edinburgh".

Sir James Hall, fourth Baronet of Dunglass, Haddingtonshire, was born on January 17, 1761. He was a great nephew of Sir John Pringle, Bart., the distinguished Army physician, a president of the Royal Society of London. Owing to the early death of Hall's father, Sir John took charge of his education. He attended the Universities of Cambridge, Geneva and Edinburgh. After extensive travel in Europe he settled down at Dunglass, though spending much time at his town house in Edinburgh. In 1786 he married Lady Helen Douglas, a daughter of the Earl of Selkirk.

Hall had been elected a member of the newly formed Royal Society of Edinburgh in 1784, and for many years took a prominent part in the affairs of the Society. He became president in 1812, being the first scientist to occupy the presidential chair. He was elected Fellow of the Royal Society of London in 1806.

Though chiefly remembered as a geologist of the Huttonian school, he was always much interested in chemistry, having been a student of Joseph Black, in Edinburgh. His first address to the Royal Society of Edinburgh was on Lavoisier's new theory of chemistry, to which he had been converted by Lavoisier himself, whom he had met a number of times in Paris.

Hall contributed a number of papers to the Edinburgh *Transactions*, chief among them being his "Account of the Effects of Compression in Modifying the Effects of Heat". This describes the long series of experiments by which he demonstrated that limestone, when heated under pressure, remains undecomposed. This paper has become a classic, and illustrates Hall's great skill as an experimentalist. Hall has been called the 'father of experimental geology', but might, perhaps more aptly, be called the 'father of geochemistry'. His skill as an experimentalist has tended to obscure the fact that he was also an extremely able field-geologist.

Hall was a man of many interests, including, in later life, politics, and he was member of Parliament for the St. Michael division in Cornwall during 1807–1812. He died in 1832, after suffering ill-health in his later years.

HOSPITAL IN-PATIENTS IN BRITAIN

A REPORT on the Hospital In-Patient Enquiry for 1959 gives provisional figures for that year and some comparisons with earlier years*. The report is based on data provided by hospitals (other than psychiatric hospitals) in the National Health Service, on forms giving a confidential summary of the case records of a 10 per cent sample of discharges (the term includes deaths). The purpose of the inquiry is to provide statistics to assist the administration of the hospital service and to supplement other statistics about mortality and illness in the community. It is organized jointly by the Ministry of Health and the Central Register Office. 1959 was the second year in which the inquiry had almost complete coverage of the relevant hospitals in England and Wales.

The tables in the report show the diagnostic distribution of case discharges in 1959 and in each year back to 1955, regional figures for selected important conditions back to 1956, regional figures for maternity cases according to the type of maternity care received, and the distribution of the cases in the 1959 sample by sex, age and diagnosis. It also includes the estimates of the population of hospital regions by sex and age at June 30, 1959.

There were, in all, 3,664,100 discharges from the relevant hospitals in 1959, or 807·3 per 10,000 population, compared with 3,554,700, or 788·0 per 10,000 in 1958, an increase of 2·4 per cent. The estimated numbers of discharges for most common causes of admission to hospital showed some increase, though much of this was probably due to more efficient use of hospital services rather than to increased illness.

Respiratory tuberculosis continued to decrease. There were 44,300 discharges in 1959, 9·8 per 10,000 population, compared with 48,800 and a rate of 10·8 in 1958. The rates for males fell in all regions except Liverpool, where an intensive mass radiography campaign was held early in the year.

---

* Ministry of Health and General Register Office. Report on Hospital In-Patient Enquiry for the year 1959. Part 1: Preliminary Tables. Pp. 16. (London: H.M. Stationery Office, 1961.) 1s. 6d. net.

There were 2,200 cases of acute poliomyelitis discharged, or 0·5 per 10,000 population, 1,000 fewer than in 1958; there has also been a steady rise in hospital discharges for cancer of the lung, from 22,400, 5·0 per 10,000 population, in 1955, to 30,600, 6·7 per 10,000, in 1959. Discharges for other tumours benign and malignant, have remained fairly steady.

Discharges for coronary disease continued to rise. The 1959 figure was 56,600 (12·5 per 10,000 population), 6,800 more than in 1958. For other heart diseases and hypertensive disease, combined, there were 5,500 fewer discharges in 1959 than 1958. 44,600 cases of varicose veins were discharged, 9·8 per 10,000 population, compared with 40,900 and 9·1 in 1958.

Figures for influenza, bronchitis and pneumonia all showed an increase over 1958, but whereas hospital cases of influenza fluctuate (2,600 in 1955 and 1956, 22,200 in 1957, 4,200 in 1958 and 10,000 in 1959), pneumonia and bronchitis have increased steadily from 58,000 and 35,400, respectively, in 1955 to 81,000 and 60,200 in 1959.

In the two years since 1957, discharges for head injuries increased by 20 per cent to 82,300, a rate of 18·1 per 10,000 population, and other injuries by 13 per cent to 219,200 and a rate of 48·3.

The number of maternity discharges in 1959 was 612,400, being 80·2 per 100 births, compared with 599,000 and 75·9 in 1958. Of all births, 60·5 per cent took place in hospital compared with 57·5 in 1958.

ORIGINS OF PETROLEUM

SIR ROBERT ROBINSON has put forward an intriguing new theory suggesting a duplex origin of mineral oils.* The prevailing view is that biologically derived organic matter aged and was transformed into petroleum; but the organic chemistry of this supposed petroleum has never been satisfactorily worked out.

In place of this conception, Sir Robert suggests a duplex mixture which, wherever it was situated, had plenty of time to find its way to the littoral regions of the oceans and there to become admixed with organic life. As in the full biological theory, life would be promoted by salts brought down by the rivers.

It was indicated by Oparin and Urey that the primeval atmosphere was probably largely methane, carbon dioxide and ammonia and the temperatures rather high. The atmosphere of Venus may be similar. It contains much carbon dioxide, and Hoyle has suggested that the clouds could consist of oil. Organic matter has been found in meteorites. Loss of hydrogen from methane would yield hydrocarbons and the thermodynamic equilibrium would be disturbed by escape of hydrogen from the atmosphere. Urey and Miller have shown that simple amino-acids, for example glycine and aspartic acid, can be produced in the laboratory naturally, by irradiation of such a mixture after cooling. Quite recently, Bahadur and Srivastava have made peptide from the same amino-acids by photosynthesis in aqueous solutions. The simple, early non-chlorophyllic organisms might well have used hydrocarbons as a source of energy, and possibly become covered with oil concentrated near the shores. It is hard to see that the distribution of oil which is now observed presents any insuperable obstacle. Almost all geochemical distributions are curiously uneven. The primeval oil may have been on the surface of the seas and brought to shore by solids such as small organisms and rock dust combined with the action of the tides. The release from miscelles, as suggested by Baker, is another possibility.

There are several mechanisms for straight-chain synthesis. Among these the most likely are the Fischer-Tropsch and oxo-synthesis. If olefines were present, or developed from products of oxo-synthesis, they could react with carbene to alkyl*cyclo*-propanes. The latter are known to give straight-chain α-olefines on pyrolysis as there is ample room for isomerization, branch-chain synthesis, aromatization and other cyclization, introduction of nitrogen and sulphur and so on in varied and inevitable side reactions.

NEW AFTERGLOW EMISSION ASSOCIATED WITH METASTABLE NITROGEN ATOMS

By L. HERMAN and R. HERMAN

Observatoire de Paris-Meudon, France

ATOMIC two-body recombination is of importance if the atomic concentration is small enough. This is known to occur in interstellar space, for example. In laboratory experiments three-body recombination is usually the most important. When the gas pressure is small, the atoms diffuse towards the wall where they are de-activated before they recombine by two-body collisions. Addition of an inert gas reduces the diffusion effect. One may then observe strong emissions of atomic lines of forbidden transitions or atomic recombination spectra. These emissions are usually characterized by a strong afterglow since the recombination processes are slow or the life-times for the forbidden transitions very large, of the order of seconds. In the present article a new example is given of atomic recombination involving excited nitrogen atoms.

The discharge tube is a 1-l. glass bulb with two side-tubes sealed in. One contains a 2-mm. diameter tungsten rod which may be used as an internal electrode. The second tube contains phosphorus pentoxide and sodium trinitride powder. Phosphorus pentoxide eliminates the last traces of water vapour; sodium trinitride is used to produce small quantities of pure nitrogen.

In some experiments, in order to improve and accelerate the purification of nitrogen, a portion of the inner surface of the glass bulb has been coated with a thin layer of solid sodium. After careful evacuation, the glass bulb is filled with pure xenon

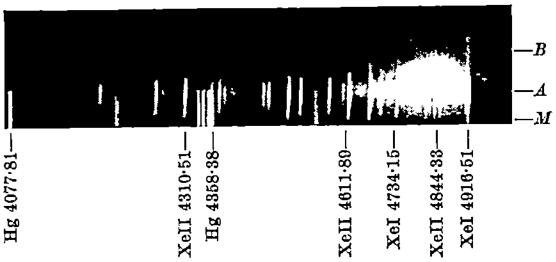

Fig. 1. Afterglow of a nitrogen-xenon mixture. *A*, high frequency discharge spectrum showing the XeI lines and the semi-continuous band system; *B*, short duration afterglow emission spectrum; *M*, mercury comparison spectrum

gas at a pressure of 20 mm. mercury and sealed off. The discharge and the afterglow spectra have been recorded using a conventional pulse technique and a rotating disk. The high-frequency generator had a pulse frequency of 50 cycles per sec. and a pulse duration of 10 μsec. The high frequency–high voltage output was applied directly to the tungsten electrode of the glass bulb.

The rotating disk was driven by a synchronous electric motor having the same frequency as the pulse generator. It is possible to obtain either the discharge or the afterglow spectrum, at the selected time delay, using the phase-shift circuit of the generator. Often it is interesting to obtain simultaneously the discharge and the early afterglow spectra. This can be achieved if the edge of the slit of the rotating disk is perpendicular to the slit of the spectrograph, and has been done for the spectrum shown in Fig. 1. Such a comparison is often useful: it is then quite certain that the experimental conditions are exactly the same for both the discharge and the afterglow spectra.

Fig. 1 shows a print of the spectrum obtained with the pulse generator, the rotating disk, and a glass spectrograph of *f*/8 aperture. The exposure time was 3 hr. This spectrum is obtained with a single exposure in which half the slit admitted light from the discharge (during the pulse of the generator), and the other half of the slit the early afterglow emission. The discharge spectrum *A* shows most of the XeI lines located in the blue and in the violet (the XeII lines in the red are not recorded in this spectrum). The remarkable feature is that the afterglow emission does not seem to be much excited in the discharge. The afterglow spectrum shows a vibrational structure which seems to merge into a continuum near 4790 Å. This continuous emission extends to about 4600 Å.

The experimental fact gleaned from Fig. 1 is that the semi-continuous band system has about the same intensity in the discharge as in the afterglow. It suggests strongly that the emission is associated with a slow reaction. It is emitted only if nitrogen is present. The emitting molecule is very likely diatomic. Any polyatomic molecule would be dissociated in the discharge in a matter of seconds. Since xenon and nitrogen are both necessary for the emission, the diatomic molecule is either an unstable XeN or one of the weakly bound excited nitrogen molecules.

Other semi-continuous spectra which also seem related to atomic forbidden transitions have been found in mixtures of xenon and oxygen. For example, there is a very strong green emission related to the forbidden 5577·35 Å. ($2p^4\,{}^1D - 2p^4\,{}^1S$) line. Contrary to the emission of Xe + N_2 investigated here, the 5577·35 Å. oxygen line lies at the limit of the semi-continuous emission. It corresponds to the asymptotic portions of the upper and lower molecular potential curves. In the present case (Xe + N_2) the wave-length limit should be at 5200 Å., corresponding to the forbidden transition of atomic nitrogen $2p^3\,{}^4S^0 - 2p^3\,{}^2D^0$. Actually, the short wave-length limit is about 4920 Å. This differs from the forbidden nitrogen line by 1,383 cm.$^{-1}$ = 0·171 eV.

There is, however, a large difference in the life-times for these two lines. The transition probability for the oxygen green line is 1 sec.$^{-1}$ while that of the nitrogen λ 5200 Å. line is 8×10^{-5} sec.$^{-1}$, about 10^4 times smaller. This difference may be the reason why the 5200 Å. line is not observed in the laboratory.

The emission may be due to recombination of two metastable or normal nitrogen atoms. The lowest states of neutral nitrogen are:

$$\mathrm{N}(2p^3\,{}^4S^0),\ \mathrm{N}(2p^3\,{}^2D^0) \text{ and } \mathrm{N}(2p^3\,{}^2P^0)$$

having the energies:

$$0{\cdot}00 \text{ eV., } 2{\cdot}37 \text{ eV. and } 3{\cdot}56 \text{ eV.}$$

The possible recombination processes are:

$$\begin{array}{l} M + \mathrm{N}({}^4S) \rightarrow M\mathrm{N}(S) \\ M + \mathrm{N}({}^2D) \rightarrow M\mathrm{N}(D) \\ M + \mathrm{N}({}^2P) \rightarrow M\mathrm{N}(P) \end{array}$$

where *M* is a nitrogen or xenon atom. The letters *S*, *P* and *D* in the right side next to *M*N indicate molecules built up with nitrogen *S*, *D* and *P* atoms. As is customary, we shall assume that the pairs of colliding atoms follow a very shallow potential energy curve.

If *M* is a nitrogen atom, the shallow potential energy curves will intersect other potential energy curves of stable molecular states, in the region of internuclear distances $r > r_e$.

For $\mathrm{N}({}^4S) + \mathrm{N}({}^4S)$, for example, intersections occur with $B^3\Pi_g$ at $v \geqslant 12$, $Y^3\Sigma_u^-$ at $v > 7$, $\alpha'\,{}^1\Sigma_u^-$ at $v > 6$, $a^1\Pi_g$ at $v > 6$, . . . For $\mathrm{N}({}^4S) + \mathrm{N}({}^2D)$, an intersection occurs with $C^3\Pi_u$ at $v > 3$.

However, there should be a chance for direct transitions between the unstable repulsive potential curves. The spectra emitted will be located in the following wave-length regions:

$$\begin{array}{lll} \mathrm{N}({}^4S) + \mathrm{N}({}^2D) \rightarrow & \mathrm{N}({}^4S) + \mathrm{N}({}^4S) + & h\nu \\ \quad 12{\cdot}139 \text{ eV.} & \quad 9{\cdot}756 \text{ eV.} & 2{\cdot}383 \text{ eV.} \\ \mathrm{N}({}^4S) + N({}^2P) \rightarrow & \mathrm{N}({}^4S) + \mathrm{N}({}^4S) + & h\nu \\ \quad 13{\cdot}331 \text{ eV.} & \quad 9{\cdot}756 \text{ eV.} & 3{\cdot}575 \text{ eV.} \\ \mathrm{N}({}^4S) + \mathrm{N}({}^2P) \rightarrow & \mathrm{N}({}^4S) + \mathrm{N}({}^2D) + & h\nu \\ \quad 13{\cdot}331 \text{ eV.} & \quad 12{\cdot}139 \text{ eV.} & 1{\cdot}192 \text{ eV.} \\ \mathrm{N}({}^2D) + \mathrm{N}({}^2D) \rightarrow & \mathrm{N}({}^4S) + \mathrm{N}({}^4S) + & h\nu \\ \quad 14{\cdot}522 \text{ eV.} & \quad 9{\cdot}756 \text{ eV.} & 4{\cdot}766 \text{ eV.} \\ \mathrm{N}({}^2D) + \mathrm{N}({}^2D) \rightarrow & \mathrm{N}({}^4S) + \mathrm{N}({}^2D) + & h\nu \\ \quad 14{\cdot}522 \text{ eV.} & \quad 12{\cdot}139 \text{ eV.} & 2{\cdot}383 \text{ eV.} \\ \mathrm{N}({}^2D) + \mathrm{N}({}^2D) \rightarrow & \mathrm{N}({}^4S) + \mathrm{N}({}^2P) + & h\nu \\ \quad 14{\cdot}522 \text{ eV.} & \quad 13{\cdot}331 \text{ eV.} & 1{\cdot}191 \text{ eV.} \end{array}$$

In these equations it is assumed that the emission takes place while the atoms are on the horizontal asymptotic part of the potential curve. If transitions from the shallow minima of the unstable potential curves are considered, slightly different wave-lengths may be obtained. This would explain the difference of 1,383 cm.$^{-1}$ discussed above.

Then our afterglow spectrum would correspond either to the first or the fifth process. The first reaction is more likely since the number of $\mathrm{N}({}^2D)$ atoms is much smaller than that of $\mathrm{N}({}^4S)$ atoms.

CHEMISORPTION AT SOLID-LIQUID INTERFACES

By A. R. BURKIN and G. HALSEY

Department of Metallurgy, Royal School of Mines, Imperial College of Science and Technology, London, S.W.7

ADSORPTION of solute molecules or ions from aqueous solutions at a solid surface may result in strong electron interaction between one or more atoms of the adsorbed material and the solid. In such cases water molecules must be displaced and if the adsorption sites correspond to close proximity of metal ions in the solid lattice the adsorption process is formally similar to the first stage in the formation of a co-ordination complex compound. For a simple hydrated metal ion M^{n+} and ligand L, assumed here to be uncharged, this is represented by the following reaction with equilibrium constant K_1:

$$[M(\mathrm{H_2O})_x]^{n+} + L \rightleftharpoons [M(\mathrm{H_2O})_{x-y}\,L]^{n+}$$

If this model of adsorption is applicable there should be a correlation between the extent of adsorption and the value of K_1 for an appropriate equilibrium in solution. Since the environment of a metal ion controls its electron energy-levels, direct comparison is impossible, but by use of a simple argument in the interpretation of some adsorption isotherms it is shown below that the model predicts the observed behaviour.

If certain transition metal ions are placed in order of increasing values of K_1 with a ligand which gives metal-oxygen or metal-nitrogen bonds, it is found that the order is the same for many different ligands (the Irving-Williams series). The values of log K_1 for complex formation with ammonia, extrapolated to infinite dilution, at 30° C. are [1] for Cu(II), 4·01; Ni(II), 2·67; and Zn(II), 2·18. It may be confidently predicted, therefore, that with primary aliphatic amines copper will form more stable complexes than will the other two metals, and the complexes of nickel will be slightly more stable than those of zinc. Thus such an amine should be adsorbed more strongly from an aqueous solution by copper oxide than by nickel oxide and more strongly by this than by zinc oxide, if the arguments presented above are correct.

Adsorption of *n*-dodecylamine on quartz occurs from solutions of *p*H around 9 by attachment of alkylammonium ions to the solid[2,3]. At higher amine concentrations multilayer formation occurs by abstraction of uncharged amine molecules. The results presented in Fig. 1 show that cupric, nickel and zinc oxides adsorb amine molecules, not the ions. The curves show the variation with *p*H of the minimum concentration of total amine (molecules and ions) in solution capable of giving 'pick up' of solid particles of the oxide of size such that they pass through a sieve with openings 0·211 mm. but not through one with 0·152 mm. openings. 'Pick up' is said to occur when the particles under the amine solution adhere so firmly to an air bubble that they do not readily break away when the bubble is raised through the liquid. For particles of similar size and mass it is generally agreed that pick up occurs when the surface coverage with a particular reagent reaches a certain value which depends on the system. The pick up curves for the three metal oxides correspond to lines of constant free-amine concentration in the solution. The analogous curve for quartz corresponds to constant alkylammonium ion concentration in solution. The lack of adsorption of the ions by the metal oxides from solutions of low amine concentration is probably associated with the much higher density of negative charge at the surface of quartz in solutions of *p*H 9–10.

In Fig. 2 adsorption isotherms measured at 30° C. are given for *n*-dodecylamine on cupric, nickel and zinc oxides. A full discussion of these will be presented elsewhere. In the case of cupric oxide a well-defined flattening of the curve corresponds to completion of a monolayer, and at higher amine concentrations multilayer formation occurs. Zinc and nickel oxides do not show completion of the monolayer but analysis of the curves indicates multilayer formation in the same region of amine concentration in solution as gives multilayers on cupric oxide. While the monolayer is being formed it is clear that the ability to adsorb amine from solution increases in the order ZnO < NiO < CuO.

The entropy changes on adsorption of amine to the metal oxides before completion of the monolayer will be of similar magnitude in each case. The enthalpy changes will, therefore, also be in the order CuO > NiO > ZnO as will the strengths of the bonds between the metal ions and the amine adsorbed relative to those between the metal ions and water. The strength of the bond between a metal ion and

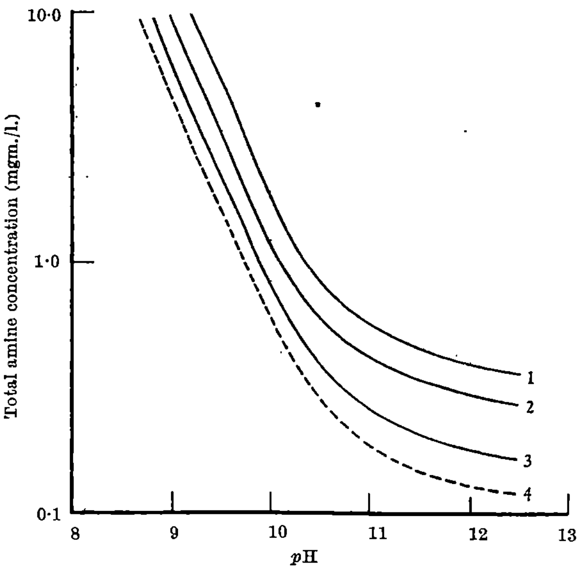

Fig. 1. Bubble pick-up curves for *n*-dodecylamine and (1) ZnO, (2) NiO, (3) CuO. Curve (4) shows the slope of lines of constant free amine concentration

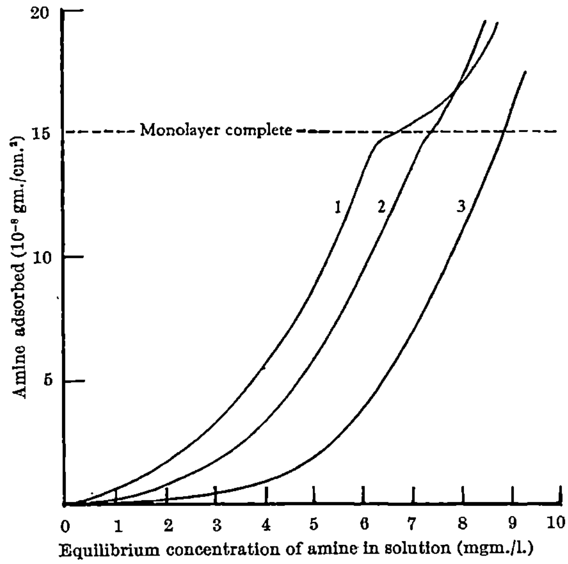

Fig. 2. Adsorption isotherms (30° C.) for *n*-dodecylamine in 10^{-3} *N* sodium perchlorate solution at *p*H 9·5 on (1) CuO, (2) NiO, (3) ZnO

ligand depends on the electronic structure of each. In particular, the ability to form π-bonds will significantly increase the bond-strength. Molecules containing an element such as sulphur in a low valency state can accommodate electrons from suitable levels in the metal ion in vacant levels and so give π-bonds. If the metal ions are in a solid lattice the electrons available for interacting with the ligand may either be isolated on the individual metal ions or they may be held in bands associated with the whole crystal if the solid is a semiconductor. In the latter case the relevant electron energy will be that at the surface and sensitive to lattice impurities in that region.

A large amount of data exists[4] showing that mercaptans, dialkyl sulphides, xanthates, dithiocarbamates and similar compounds containing divalent sulphur are adsorbed very strongly from solutions of suitable *p*H by solids containing metal ions which are in a suitable electronic state to form strong bonds with sulphur. With an oxidizing ion such as divalent copper, electron transfer often results, giving oxidized ligand and cuprous ions, whereas cuprous oxide, for example, simply adsorbs the reagent. If a solid has both anodic and cathodic areas on the surface, different adsorption behaviour would be expected at each kind of surface. In the case of galena and xanthate, adsorption occurs at the anodic regions[5] and greatly increased amounts are adsorbed when anodic bias is applied to the solid. The electron energy-levels are raised under anodic conditions so that the energy of electrons in the solid available for π-bond formation with vacant ligand orbitals is increased.

The views on the factors controlling chemisorption from solution set out above are strongly supported by experimental evidence. It is therefore possible to predict what reagents and treatment of the solid are likely to give strong adsorption under suitable conditions. This is of interest in infestigating the froth flotation process for separating minerals.

We thank the Department of Scientific and Industrial Research for a maintenance grant to one of us (G. H.) and the University of London Central Research Fund for a liquid scintillation counter.

MODIFIED CELLULOSE ION EXCHANGERS AND THEIR USE IN RIBONUCLEIC ACID FRACTIONATION

By Dr. L. BOSCH, Miss G. van der WENDE and Dr. H. BLOEMENDAL

Department of Biochemistry, The Netherlands Cancer Institute, Antoni van Leeuwenhoek-Huis, Amsterdam

SINCE their introduction by Peterson and Sober in 1956[1] modified cellulose ion exchangers have been widely applied for the fractionation of polyelectrolytes like nucleic acids and proteins. Two types of resins particularly proved to be of value. The first one is an ion exchanger containing basic groups derived from triethanolamine bound to cellulose through reaction with epichlorohydrin. This resin, called Ecteola-cellulose, has frequently been used for nucleic acid fractionation[2–4].

A second type of cellulose adsorbent displayed particular merits for the chromatographic separation of proteins. It contains carboxymethyl (CM-cellulose), diethylaminoethyl (DEAE-cellulose), triethylaminoethyl (TEAE-cellulose) and phosphate (P-cellulose) groups. Among these DEAE-cellulose may also be used for the resolution of nucleic acid mixtures[5].

The obvious need for improvement of the available fractionation techniques in connexion with metabolic work on nucleic acids, urged us to explore the possibilities of cellulose ion exchangers more systematically.

In two earlier papers[6,7] we described a fractionation and purification of microsomal (*m*-RNA) and soluble ribonucleic acid (*s*-RNA) from rat liver on the resin Ecteola. Although the results were valuable for the establishment of certain metabolic interrelationships between the two kinds of nucleic acids, definite disadvantages of this resin soon became apparent. Following adsorption of a polymer of relatively high molecular weight (for example, microsomal RNA) on Ecteola columns, complete recovery cannot be achieved without application of eluants of high *p*H, degradative for RNA, and destroying the secondary structure of DNA. Consequently, the value of

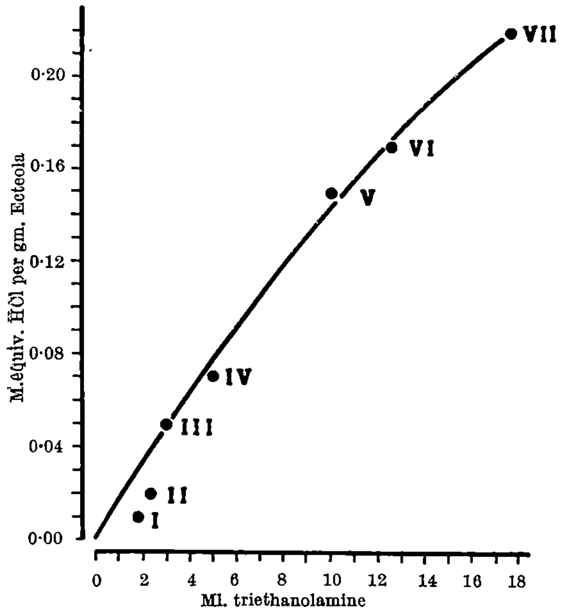

Fig. 1. Relationship between the amount of triethanolamine used for the preparation of Ecteola and the number of groups introduced as determined by potentiometric titration with hydrochloric acid. The resins were prepared as described in the text and designated Ecteola I to VII

Ecteola is rather limited although this resin is useful for the fractionation and isolation of smaller poly- and oligo-nucleotides and for analytical purposes. It is conceivable that a reduction in the density of binding sites on the exchanger would result in a weakening of the binding force between resin and the adsorbed polyanion. As a result the latter might then be eluted from the column by increasing the ionic strength of the eluant without necessarily raising the *p*H.

As an alternative such a weakening might be achieved by reducing the basicity of potential binding groups by introducing weaker bases than triethanolamine.

In this investigation both lines of approach have been followed. Various Ecteola resins with decreasing nitrogen content have been prepared and their capacities to fractionate soluble and microsomal RNA from rat liver have been compared. In addition, a new class of resins has been prepared by introducing nucleosides instead of triethanolamine into cellulose; the results of some preliminary fractionation experiments with the latter type of resins will be presented.

Experimental : Preparation of Ecteola-cellulose. Whatman cellulose powder (ashless, standard grade) was submitted for several hours to vigorous vibration in a sieve attached to the vibrator. Particles passing the sieve and having a diameter less than 0·05 mm. were used for the preparation of Ecteola according to Peterson and Sober[1].

Nucleoside cellulose was prepared by adding nucleoside instead of triethanolamine. Reactants were used in the following ratio: Whatman powder, 1 gm.; nucleoside, 1·9 m.mole; sodium hydroxide, 1 gm.; epichlorohydrin, 1 ml.; water, 2·5 ml.

Seven Ecteola resins were prepared according to Peterson and Sober[1], starting with constant amounts of cellulose (30 gm.) and epichlorohydrin (30 ml.) but increasing amounts of triethanolamine (1·75–17·5 ml.). Nitrogen content of the preparations as determined by potentiometric titration with hydrochloric acid, increased almost linearly with the amounts of triethanolamine, as shown in Fig. 1. Kjeldahl analysis yielded rather inaccurate results, probably due to the fact that very prolonged periods of heating with concentrated sulphuric acid were required for complete destruction. In most cases, however, about 90 per cent of all nitrogen groups determined by the Kjeldahl analysis could be accounted for by hydrochloric acid titration.

Fractionation of microsomal RNA from rat liver. Microsomal RNA was isolated from rat liver by means of phenol extraction[8,9], dialysed against 0·01 *M* phosphate, *p*H 5, and submitted to chromatography on the various Ecteola preparations. Some of the elution patterns, representative for our work on microsomal RNA, are illustrated in Fig. 2.

With increasing nitrogen content of the resins, a shift in these patterns towards the alkaline region is observed, and from Ecteola V onwards the amount of RNA requiring alkali for its elution rises. On Ecteola VII all the RNA emerges from the column in the alkaline region, indicating that fractionation experiments on resins of one particular nitrogen content only may not always yield a clear picture of the heterogeneity of the samples under investigation. Furthermore, it can be concluded from Fig. 2 that a fairly large proportion of *m*-RNA is recovered from various resins by sodium chloride elution. This fraction was designated as m_2-RNA, which means *m*-RNA recovered by washing with salt, although the varying proportions with which it is eluted in the salt region on various Ecteolas (Fig. 2) throws doubt on the homogeneity of this fraction. Ultracentrifugal analysis revealed that it is polydisperse[10].

Fractionation of soluble RNA. In earlier experiments[6] it was shown that a fraction of soluble RNA, which is involved in the transfer of amino-acids to the microsomes, also appeared in the salt region when fractionated on Ecteola. The question could therefore be raised whether microsomal RNA contains

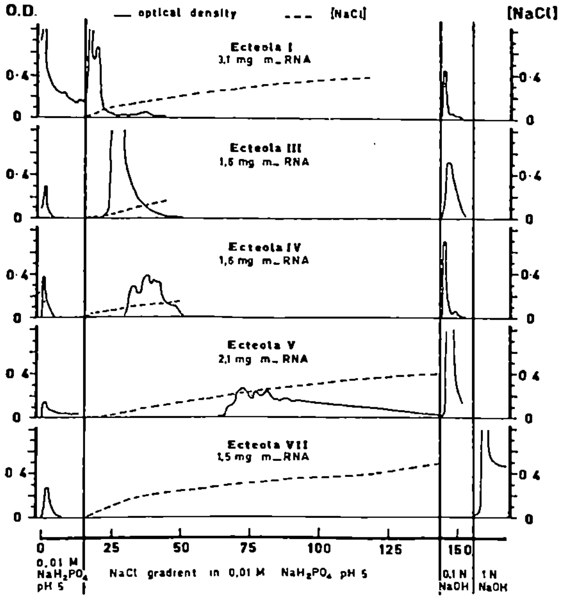

Fig. 2. Fractionation of microsomal RNA on Ecteola resins with increasing nitrogen content. Columns of 7 cm. length and 0·8 cm. diameter. A linear gradient elution system was established by applying a stock of 1 *M* NaCl–0·01 *M* phosphate (*p*H 5) solution and a mixing flask containing 1 l. of 0·01 *M* phosphate (*p*H 5). Optical density (O.D.) was read at 260 mμ

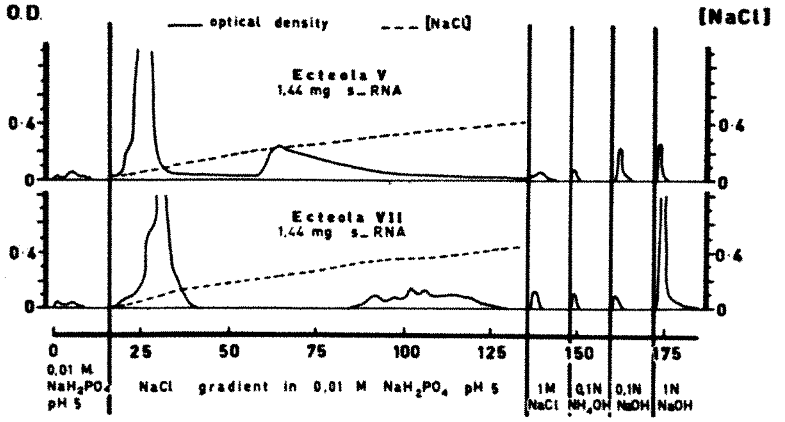

Fig. 3. Fractionation of soluble RNA on two Ecteola resins. For conditions, see legend, Fig. 2

soluble RNA, either as a native component or as a contamination due to inefficient washing of the microsomes. Support for the former assumption may be derived from communications by Smith *et al.*[11,12], who found that mouse-liver microsomes contain RNA (comprising 10–20 per cent of the total *m*-RNA) which will accept amino-acids, when incubated with enzymes at *p*H 5 under the usual conditions. Hence the behaviour of *s*-RNA on various Ecteola resins was examined, and some of the results are presented in Fig. 3. Chromatography of *s*-RNA on Ecteola V yields a fraction, earlier designated as s_3-RNA [6], which carries amino-acids and is indistinguishable from m_2-RNA, when fractionated similarly on Ecteola V.

A comparison of the elution patterns of *s*- and *m*-RNA on Ecteola VII, however, clearly demonstrates the non-identity of the fractions s_3 and m_2, and stresses once more the importance of using resins with varying densities of binding sites. A further characterization of the two fractions will be published elsewhere[10].

Two modifications in the elution procedure have been attempted: gradient elution with magnesium chloride in 0·01 *M* phosphate buffer of *p*H 5, and elution with increasing concentrations of phosphate, keeping the *p*H constant at 5. When *m*-RNA was fractionated on Ecteola IV only 10 per cent of the material could be recovered by applying the magnesium chloride gradient, the remaining 90 per cent appearing in the alkaline region. Similar results were obtained when the ionic strength was increased by applying a phosphate gradient.

Cellulose ion exchangers containing binding groups of lower basicity. The ease with which all kinds of groups may be introduced into cellulose suggested that nucleoside instead of triethanolamine might also react with cellulose through epichlorohydrin. According to this idea, four new ion exchangers have been prepared from adenosine, guanosine, cytidine and uridine, respectively. Preliminary results of *m*-RNA fractionation on the adenosine resin are illustrated in Fig. 4. More than 50 per cent of the polynucleotide adsorbed was recovered by applying a sodium chloride gradient elution system, the remainder by washing with ammonia and sodium hydroxide. *m*-RNA recovered by means of sodium chloride from the adenosine column and re-submitted to chromatography emerged from the column in exactly the same position, demonstrating a good reproducibility of this type of resin. Batches prepared at different times, however, did not always yield strictly identical fractionation patterns, necessitating a primary check before any new batch is going to be used.

Although the fractionation of *m*-RNA on guanosine cellulose has not been fully investigated so far, it appeared that *m*-RNA, when dissolved in 0·01 *M* phosphate, *p*H 5, is retained very weakly by the resin. Possibly elution has to be performed with buffers of very low ionic strength.

Uridine cellulose and particularly cytidine cellulose bind large proportions of *m*-RNA, recoverable by elution with alkali only.

Discussion. Ecteola and DEAE have a limited value for the fractionation of nucleic acids only due to the high *pK′* values of the two types of resins. (*pK′* of DEAE (in 0·5 *M* sodium chloride) is 9·5, that of Ecteola 7·5. Cellulose resins prepared from monoethanolamine (*pK′* 9) instead of triethanolamine (*pK′* 8·0) retained RNA more strongly than Ecteola did.) More favourable results might be expected by weakening the binding force between absorbent and polymer, for example, by replacing heteropolar linkages by van der Waals forces, hydrogen bonds, etc. In fact, a resin consisting of an insoluble polynucleotide seemed to meet these requirements ideally. Such a resin may be prepared by maximal loading of Ecteola with a synthetic polynucleotide of high molecular weight. Polyadenylic acid with a molecular weight of about 400,000, for example, is strongly bound by Ecteola[7], and can be recovered only by eluting with alkaline solutions. So far, exchangers of this type have not been investigated in this laboratory due to the fact that large amounts of polynucleotides are needed and were not available to us at the time. As an alternative, nucleosides were introduced into cellulose through reaction with epichlorohydrin, and preliminary results demonstrated that resins with satisfactory exchanging capacities were obtained. Of the four types of resins prepared, the purine cellulose exchangers showed the most promising fractionating properties. Uridine and cytidine cellulose retained

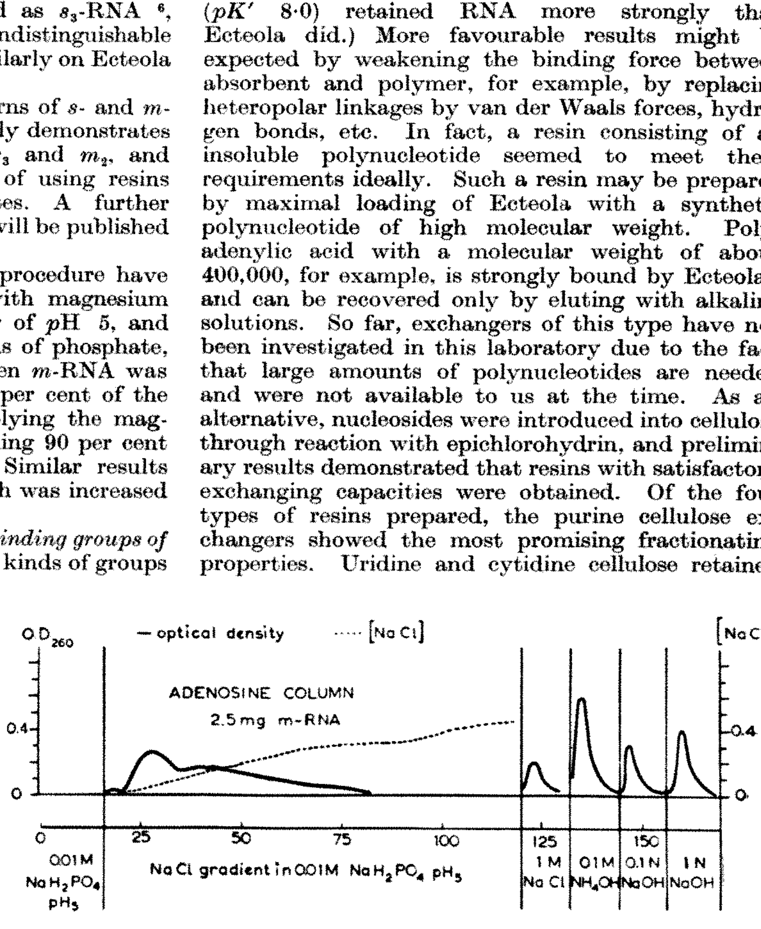

Fig. 4. Fractionation of microsomal RNA on adenosine cellulose. Column of 10 cm. length and 0·8 cm. diameter

m-RNA too strongly, and do not seem to have particular advantages over Ecteola.

The chromatographic behaviour of *m*-RNA on adenosine- and guanosine-cellulose is in accord with the lower dissociation constant of the NH_2-group of guanosine (pK'_a 1·6) as compared with that of adenosine (pK'_a 3·45) (ref. 13).

The extent to which ring opening of the purine and pyrimidine moieties occurs during preparation of the resin remains to be investigated. Strong alkali is required, and the temperature rises to more than 100° C. during the exothermic reaction between cellulose, epichlorohydrin and nucleoside. Potentiometric titration of adenosine cellulose did not reveal the presence of any additional basic groups and the pK'_a of the resin is the same as that of free adenosine. This may indicate that the purine structure remained unaltered during preparation of the ion exchanger. The strong retention of *m*-RNA by pyrimidine cellulose, however, throws doubt on this question so far as the pyrimidines are concerned.

DIMER FORMATION AND THE TRANSFER OF GLYCEROL ACROSS THE ERYTHROCYTE MEMBRANE

By DR. W. D. STEIN*

Department of Colloid Science, University of Cambridge

A NUMBER of cell membranes have been shown to possess specialized systems which accelerate the movement down the concentration-gradient of specific metabolites. In the absence of such systems, these metabolites can cross the membrane slowly or not at all. Among such 'facilitated diffusion' systems[1] are those concerned in the movement of glucose into the human erythrocyte[2] and into muscle diaphragm[3] and the inward movement of sodium ions during the passage of the nerve impulse[4]. Most models that have been suggested for facilitated diffusion have involved hypothetical carriers in the cell membrane. The present investigation of the system which transfers glycerol across the human erythrocyte membrane[5] was initiated in the hope of isolating such a glycerol carrier. However, during the course of this work it has become clear that a model can be suggested which accounts for the facilitated diffusion of glycerol, without requiring the assumption of any membrane carrier at all.

It is perhaps useful to recall what constitutes the normal barrier to the movement of a molecule such as glycerol across the membrane, in the absence of any facilitated diffusion system[6]. The three hydroxyl groups of glycerol form strong hydrogen bonds with water. These hydrogen bonds anchor the glycerol in the aqueous phase, hindering its entrance into the hydrophobic lipid region of the membrane and hence reducing the rate at which it crosses the membrane. The membrane carriers that some previous workers have postulated have been 'alternative-hydrogen-bond formers' which can form hydrogen bonds with the glycerol molecules, competing with the water molecules. The carrier-glycerol complex has then its hydrogen-bonds internally saturated and can enter the cell membrane largely free of attached water molecules (Fig. 1*a*).

However, another method by which the glycerol molecule can have its hydrogen bond-forming capacity internally saturated is as follows (I am greatly indebted to Dr. D. A. Haydon of this Department for providing me with this idea, which is the core of the present theory): Two glycerol molecules may interact to form a dimer (Fig. 1*b*). Then each can act effectively as the 'carrier' for its fellow. On this basis I have derived the proposed model. I postulate the existence in the cell membrane of sites which bind pairs of glycerol molecules, thereby concentrating them and enabling them to interact with one another to form dimers. These dimers being free of attached water molecules (but still attached to the binding sites), are enabled to enter the hydrophobic region of the membrane. Inside the membrane the dimers dissociate from the binding site and can then traverse the membrane (either as dimers or, for the most part, having dissociated again into monomers). A summary of the evidence in favour of this model is presented here. Full details will be published elsewhere.

All the present measurements of red cell permeabilities have been made using the method of Orskov[7], in which the changes in optical density of a suspension of

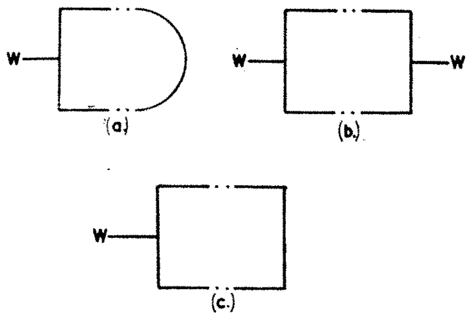

Fig. 1. Glycerol-'carrier' complexes: (*a*) glycerol + 'carrier'; (*b*) glycerol + glycerol; (*c*) glycerol + 1,3-dihydroxypropane. The left-hand molecule is, in each case, glycerol hydrogen-bonded to one water molecule

red blood cells on the addition of a solution of penetrating molecules is recorded. Analysis of the curves relating these changes in optical density with time shows that the curves are for the most part exponential functions. The half-time ($t\frac{1}{2}$) of such a curve (the time taken for the galvanometer deflexion recording the optical density to fall to half its initial value) can be related to the reciprocal of the rate at which the permeant crosses the membrane[5].

---

* Beit Memorial Research Fellow.

Postulate 1. *The glycerol acceptor site is bivalent.* (*a*) The activity of the glycerol facilitator is a function of *p*H. In Fig. 2, the reciprocal of the half-time for the entry of glycerol into the cell is plotted against *p*H for a number of buffer systems. Curve *A* in Fig. 2 is drawn on the assumption that one proton combines with a univalent glycerol acceptor to form the inactive complex, for example:

$$F + H^{+} \rightleftharpoons FH^{+} \qquad (1)$$

$$F + G \rightleftharpoons FG \qquad (2)$$

where F is the facilitator in the form capable of accepting a glycerol molecule G, FH^{+} is the inactive form, and FG is the glycerol-facilitator complex, which diffuses across the membrane. Curve B in Fig. 2 is drawn on the assumption that two protons are required to inactivate the glycerol-transferring system thus:

$$F + H^{+} \rightleftharpoons FH^{+} \qquad (1)$$

$$FH^{+} + H^{+} \rightleftharpoons FH_2^{++} \qquad (3)$$

$$FH_2^{++} \rightleftharpoons \text{inactive form} \qquad (4)$$

$$F + G \rightleftharpoons FG \qquad (2)$$

Clearly, it is this latter formulation that accords with the experimental results.

(*b*) Copper ions inhibit the glycerol facilitator. In Fig. 3, a plot of $1/t\frac{1}{2}$ against *p*M is presented. The free metal ion concentration was maintained with lysine as the metal buffer, using the copper di-lysine/lysine equilibrium. (The methodology of such diligand buffers will be presented elsewhere.) Again curve A is drawn for the metal equilibrium analogous to equations (1) and (2) involving a single copper ion, while curve B is drawn on the assumption that two copper ions are required to produce inhibition. Again the bivalent nature of the facilitator is manifest.

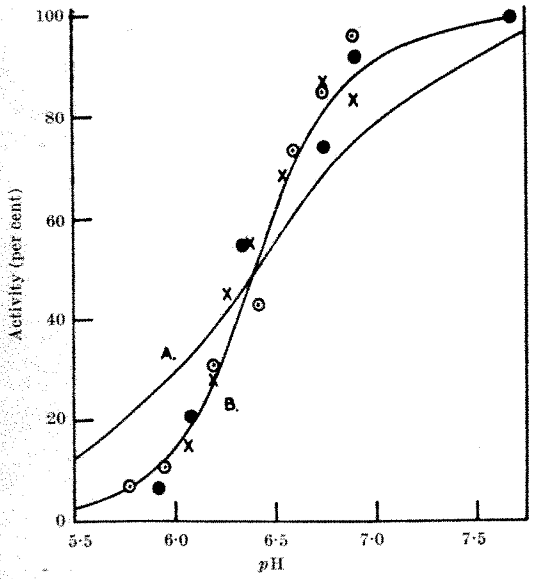

Fig. 2. Proton inhibition of the glycerol facilitator. Solid circles, histidine buffer; open circles, phosphate buffer; crosses, maleate buffer

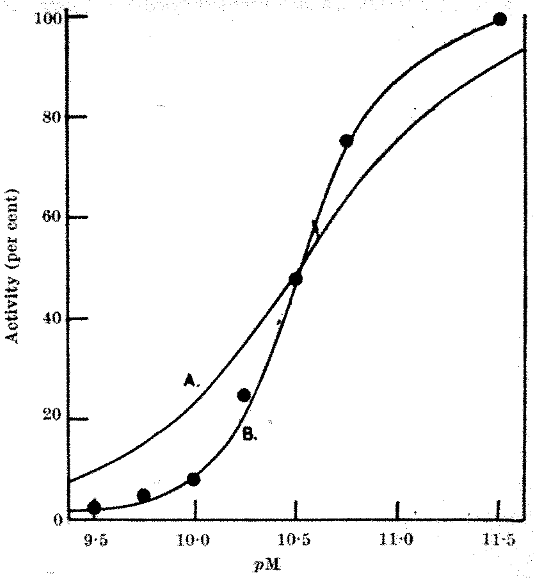

Fig. 3. Cu++ inhibition of the glycerol facilitator

(*c*) Both these experimental procedures are mute, however, as to the number of glycerol molecules present in the glycerol-facilitator complex. To investigate this, the activity of the system as a function of glycerol concentration was investigated. Red cells were equilibrated in successively increasing concentrations of glycerol and, after equilibration, a further quantity of glycerol, the same in each experiment, was injected into the suspension, and the optical density changes recorded. A theoretical analysis of the changes of cell volume with time in these conditions gave the following results:

The penetration of diethylene glycol, a molecule for which there is no reason to suspect that a facilitated diffusion system exists, is, at low concentrations, in very fair accord with the theory for penetration by simple diffusion. Somewhat surprisingly, the results for the penetration of glycerol also accord with simple diffusion theory. If, on the other hand, the theory for penetration by binding with a univalent carrier (equation (2)) is applied to the data for glycerol penetration, the absurd result is obtained that the dissociation constant of the carrier-glycerol complex is large and negative, that is, there is no affinity between glycerol and the membrane carrier. If, however, the bivalent theory is applied according to the equilibrium:

$$F + G \rightleftharpoons FG \qquad (2)$$

$$FG + G \rightleftharpoons FG_2 \qquad (5)$$

where FG_2 is the penetrating species, good accord is obtained below 1·3 M glycerol and an affinity constant of reasonable magnitude obtained.

The affinity constant for the first stage in the formation of the bivalent complex, that is, the interaction of single glycerol molecules with the acceptor sites according to equation (2) can be derived and is found to be 1·0 M. (The significance of this value will be discussed under postulate 3).

Thus it would appear that glycerol penetrates either by simple diffusion or by interaction with a bivalent acceptor, the results excluding the univalent acceptor model. But penetration by simple diffusion can also be excluded since glycerol penetration, but not that of diethylene glycol, is inhibited by protons (Fig. 2), by metal ions (Fig. 3), by substrate analogues (Fig. 4) and by a variety of other agents[8]. (See also an earlier paper[5] using a somewhat different experimental approach, where saturation of a membrane acceptor by glycerol could be demonstrated.) Thus the kinetic data demand that the facilitated diffusion system is bivalent towards the substrate glycerol as well as towards the inhibitors H^+ and Cu^{++}.

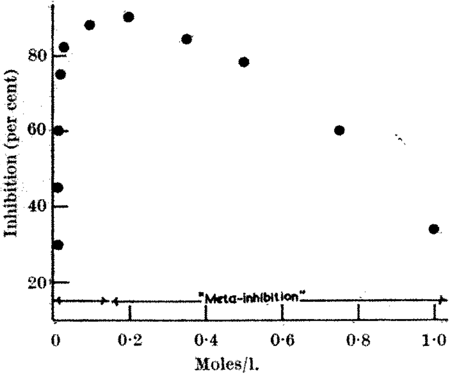

Fig. 4. Inhibition and meta-inhibition by 1,3-dihydroxypropane. Glycerol concentration fixed at 0·1 M, glycol concentration 0–1 M (abscissa)

Postulate 2. *Dimer formation leads to an increased rate of penetration.* The glycol 1,3-dihydroxypropane (or 103) is a competitive inhibitor of the glycerol facilitator. At a concentration of 0·01 M 103 (equal to one-tenth that of the glycerol added), the rate of entry of glycerol is inhibited by 50 per cent. But as the concentration of 103 is increased, the degree of inhibition passes through a maximum and then decreases again until at 1 M 103 the system is only 20 per cent inhibited (Fig. 4). This falling-off in the effectiveness of an inhibitor at high concentrations of inhibitor, or 'meta-inhibition', has here proved difficult to interpret, until now. However, let us suppose that glycerol and the glycol in the bulk of the solution interact as in Fig. 1*c* to form a dimer, albeit to a very slight extent. Then this complex will have a greatly increased rate of penetration across the membrane, as it has only one free hydrogen-bonding site available for binding to the water. On this view, then, meta-inhibition should bear no relation to the facilitated diffusion system. In fact, at concentrations of copper ions sufficient to block facilitated glycerol transfer completely, addition of 103 appears to restore the rapid transfer rate, and the same can be shown for hydrogen-ion inhibited cell preparations. Even more striking are the experiments using bovine blood. The bovine erythrocyte lacks the facilitated diffusion system for glycerol. However, if to a suspension of bovine red cells is added 0·5 M 103, there is a dramatic increase in the rate of transfer of glycerol and at a level of 1 M 103 beef red cells are, so far as their glycerol permeability is concerned, indistinguishable from normal human red cells (Fig. 5). 103 can, therefore, act as a membrane carrier for glycerol in both bovine cells and in inhibited human red cells.

Postulate 3. *The properties of the glycerol-binding site require no improbable assumptions as to energetics.*

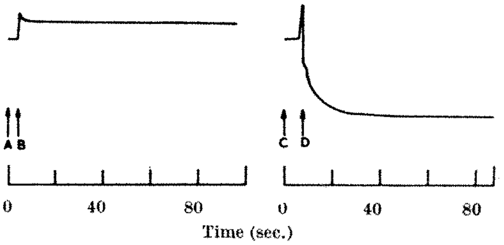

Fig. 5. Permeability of bovine erythrocytes to glycerol in the absence and presence of 1,3-dihydroxypropane. These are tracings of the experimental records of the optical density changes. At A, a suspension of bovine erythrocytes is added; and at B, glycerol injected to give a final concentration of 0·1 M. At C, the solution is changed and replaced by bovine erythrocytes equilibrated in 1 M 1,3-dihydroxypropane. At D, glycerol to 0·1 M is injected into this suspension

Direct experimental studies of glycerol dimer formation in dilute aqueous solutions are lacking. However, an estimate of the probable extent of dimer formation can be reached by considering the competition between water molecules and glycol molecules for each other according to the equilibrium:

$$AW + BW \rightleftharpoons AB + W_2 \qquad (6)$$

where A and B are hydrogen-bonding molecules interacting with water W to form AW and BW, and with each other to form AB. W_2 is the water dimer. Assume that all the hydrogen bonds AW, BW, AB and WW are equivalent and that only hydrogen bonds are concerned in the equilibrium. We can then apply the law of mass action to the equilibrium (6), and show that for a glycol concentration of 1 M and glycerol at 0·1 M, the extent of dimer formation (of the type of Fig. 1*c*) is some 0·1 per cent of the glycerol molecules. Now, a monohydroxy compound, such as in 1*c*, would be expected to penetrate the membrane about 10^4 times as fast as glycerol (ref. 6). Thus the increase in glycerol permeability in 1 M glycol should be then about $10^4 \times 10^{-3} = 10$-fold. In fact, at 1 M 103, glycerol penetration into bovine erythrocytes is speeded up some fifty-fold. This discrepancy between these two figures is not excessive considering the very drastic assumptions made in applying the law of mass action to equation (6). (In particular, the contribution to dimer formation by $-CH_2 \ldots CH_2-$ interaction has been ignored.) By similar arguments, it can be shown that to account for the experimentally observed value (1·0 M at 20° C.) of the affinity constant of single glycerol molecules for the binding site, 1,500 cal./mole of free energy must arise from binding other than at the hydroxyl group. This is a satisfactory figure for the interaction of 2 or 3 of the CH— residues of glycerol with hydrophobic sites on the glycerol acceptor.

We have seen then that interaction between glycerol and 1,2-dihydroxypropane, a molecule which can form dimers with glycerol, leads to a great increase in the rate of penetration of glycerol across the bovine erythrocyte membrane and that the extent of this increase is consistent with the extent of dimer formation to be expected in such solutions. Also, during the transfer of glycerol by the facilitated diffusion system across the human erythrocyte membrane, two glycerol molecules are bound at each acceptor site to form the penetrating complex. Finally, estimates of the energy of such interactions show that the degree of concentration of the glycerol molecules required for the system to operate is not beyond the capacity of a simple enzyme-like binding site.

The results strongly suggest, therefore, that the facilitated diffusion of glycerol occurs as a result of dimer formation between pairs of glycerol molecules bound at acceptor sites in the erythrocyte membrane.

It will be of interest to investigate whether this model can be applied more generally so as to include other facilitated diffusion systems.

I should like to thank Prof. J. F. Danielli (of King's College, London, where this work was commenced), and Prof. F. J. W. Roughton (of the Department of Colloid Science, Cambridge), for their hospitality in providing laboratory facilities for this work. Dr. D. A. Haydon and Dr. J. C. Kernohan of this Department were of invaluable help with their stimulating comments and discussion. I am indebted to the Royal Society and to Imperial Chemical Industries, Ltd., for financial assistance towards the cost of chemicals and apparatus.

SOLUBILITY OF DENATURED HÆMOGLOBIN VARIANTS IN ACID BUFFERS

By I. D. FRASER and Dr. A. B. RAPER
Pathology Department, Royal Infirmary, Bristol

WHEN methanol-fixed smears of human cord blood are exposed for 90 sec. at 37° C. to a 0·17 *M* phosphate–citrate buffer, washed, and afterwards stained with a Romanowsky dye, the degree of eosinophilic staining of individual erythrocytes varies from a negligible amount ('ghosts') to full coloration[1]. Erythrocytes in the blood of adults all appear as 'ghosts', and it is assumed that the fully coloured cells in cord blood are of fœtal type. It has not been proved that the retention of staining properties is in fact an expression of the insolubility of fœtal hæmoglobin (*F*) in the acid buffer, but we have obtained indirect evidence that this is so, and that the process allows a visualization of the hæmoglobin *F* present in individual cells.

The differential staining effect can only be obtained after denaturation of the hæmoglobin, either by methanol, acetone or heat. We therefore tested the solubility of hæmoglobins *A* and *F*, after acetone denaturation, in two ways: (*a*) after partial separation of a 1 : 1 mixture of hæmoglobins *A* and *F* by electrophoresis on 3 *MM* Whatman filter paper at *p*H 8·6, followed by immersion of the strip in acetone; (*b*) after precipitating a hæmolysate of cord blood with acetone. In the former case, immersion of the strip in the acid buffer for 2 hr. caused elution of most of the more anodically situated hæmoglobin (largely *A*), leaving the remainder (mostly hæmoglobin *F*) undissolved. In the second case, complete solution of 10 mgm. of denatured hæmoglobin *A* could be obtained in 10 ml. of the acid buffer, while with 10 mgm. of denatured hæmoglobin obtained from a cord blood hæmolysate containing 32 per cent of hæmoglobin *A*, only 28 per cent of the hæmoglobin was soluble in 10 ml. of acid buffer. Details of these experiments will be given later, but their results allowed us to proceed to investigate the distribution of hæmoglobin *F* in the erythrocytes of subjects with thalassæmia.

In smears from subjects with thalassæmia major, all the erythrocytes retained their hæmoglobin staining properties, reacting exactly as fœtal cells do (Fig. 1), when due allowance is made for the reduced thickness of many of the cells. In thalassæmia minor subjects in whom there was a measurable amount of hæmoglobin *F*, there was partial retention of hæmoglobin staining, and the degree of this did not vary from cell to cell (Fig. 2). This homogeneous picture was quite different from that given by cord blood or the blood of neonates. We interpret this as indicating that beyond the age of infancy hæmoglobins *F*

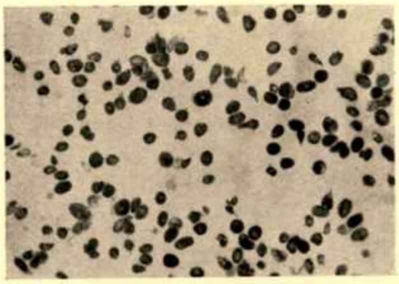

Fig. 1

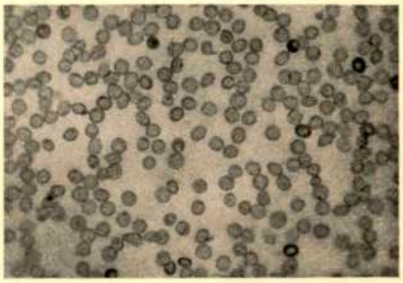

Fig. 2

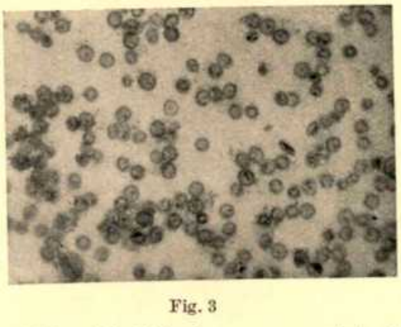

Fig. 3

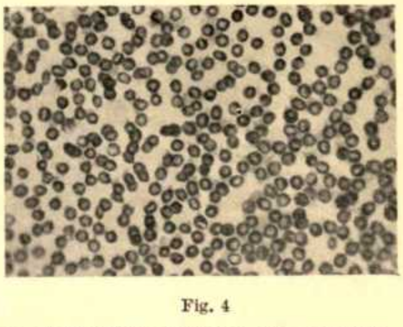

Fig. 4

Methanol-fixed blood smears, exposed to phosphate–citrate buffer at *p*H 3·4, and afterwards stained by May–Grünwald stain. (1) Thalassæmia major. (2) Thalassæmia minor. (3) Hæmoglobin *S*/*C* disease. (4) Sickle-cell trait and *A* must be synthesized together in each erythrocyte precursor. This double synthesis must occur in the marrow, the only erythropoietic organ in subjects with thalassæmia minor; and although there may be some extramedullary erythropoiesis in the case of thalassæmia major, exactly the same double synthesis must occur in other sites as in the marrow, since only one sort of cell appears in the blood.

It must be mentioned, however, that the proportion of 'insoluble' hæmoglobin retained in the erythrocytes from subjects of thalassæmia minor appeared excessive in relation to the low hæmoglobin *F* content of hæmolysates from these subjects. It is possible, therefore, that a part of their hæmoglobin *A*, though reacting normally to electrophoresis and alkali denaturation, may in fact be an aberrant molecular species, as postulated by Ingram and Stretton[2]. Some support for this is provided by the findings in congenital spherocytosis, where with proportions of hæmoglobin *F* in the same low range as in thalassæmia minor, there was no retention of hæmoglobin in the erythrocytes.

It was of interest to discover whether other hæmoglobin variants could be visualized in the same way as hæmoglobin *F*. Blood smears from subjects with various hæmoglobinopathies were submitted to the acid-lysis test, using buffers of several *p*H values. The results are shown in Table 1.

Where hæmoglobins *F* and *A* occur together, there was retention of hæmoglobin in the cells, and the degree of retention was roughly proportional to the amount of hæmoglobin *F*, with the exception, already noticed, of thalassæmia minor. The retention of hæmoglobin in the erythrocytes of a subject displaying hæmoglobin *H* is complicated by the facts that some hæmoglobin *F* was present, and that such persons are heterozygous for the thalassæmia gene. Hæmoglobins *C* and *D* are indistinguishable in their reaction from hæmoglobin *A*, while hæmoglobin *E* appears to be less soluble than hæmoglobin *A*. In the case of a subject with hæmoglobin *S*/*C* disease, every cell appeared to have retained about half its complement of hæmoglobin (Fig. 3). Since hæmoglobin *C* has been shown to be eluted from the cells of a hæmoglobin *C* trait carrier (*AC*), the insoluble fraction was presumed to be hæmoglobin *S*. Yet when the test was applied to sickle-cell trait (*AS*) subjects, carrying less hæmoglobin *S* than occurs in hæmoglobin *S*/*C* disease, almost the whole of the hæmoglobin appeared to be retained in every cell at *p*H 3·4 (Fig. 4) though all was eluted at *p*H 3·0. In sickle-cell anæmia the retention was even greater, being evident at *p*H 3·0. Some part of the retention in the latter case might be ascribed to the small amount of hæmoglobin *F* present, but this will not suffice to explain the difference between the *A* + *S* and the *S* + *C* subjects. We assume that either in its native state, or more probably during methanol denaturation, hæmoglobin *S* forms an insoluble complex with hæmoglobin *A* but not with hæmoglobin *C*.

Table 1. Retention of Hæmoglobin Variants in Fixed Erythrocytes Exposed to Acid Buffers

Cells containing hæmoglobins	Proportion of hæmoglobin *F* (per cent)	Retention of hæmoglobin in erythrocytes treated at *p*H: 3·4	3·0	2·0
A	< 1	0	0	0
F + *A* (16-week fœtus)	94	+ + +	+ +	+
F + *A* (thalassæmia major)	70	+ +	+	0
A + *F* (thalassæmia minor)	2·7–3·5	+	. . .	. . .
A + *F* (congenital spherocytosis)	3·3–3·5	0	0	0
S + *F* (sickle-cell anæmia)	8–17	+ +	+ +	0
A + *S* (30–45 per cent) (sickle-cell trait)	< 1	+ +	0	0
C + *S* (50 per cent)	. . .	+	0	0
A + *C* (40 per cent)	< 1	0	0	0
A + *D* (45 per cent)	< 1	0	0	0
A + *E* (30 per cent)	< 1	±	0	0
A + *H* (15 per cent)	3	+ +	0	0

+ + +, complete retention; + +, almost complete retention; +, about 50 per cent retention; ±, less then 33 per cent retention; 0, no retention.

THYROGLOBULIN

By Dr. A. D. LITONJUA*
Thyroid Laboratory, Massachusetts General Hospital, Boston, 14

Effect of Acid

EDELHOCH has shown that alkali produces new sedimentable species of thyroglobulin which are smaller in molecular weight than the original material[1]. It was of interest, therefore, to find out if acid media produce the same dissociation effect.

Thyroglobulin was prepared in 1 per cent concentration in three buffer solutions according to a method in ref. 2: (1) 0·1 *M* phosphate buffer at *p*H 8·0; (2) 0·25 *M* acetate buffer at *p*H 3·5; and (3) 0·1 *M* hydrochloric acid–potassium chloride buffer at *p*H 1·5. Aliquots of each of these preparations were examined in the Spinco model *E* ultracentrifuge. Viscosity measurements were made in an Ostwald viscometer using standard procedures and calculations for intrinsic viscosities (ηi), expressed[3a] in centipoises per gm. thyroglobulin ($\eta i/c.$). Experimental temperature was 25° C.

The difference in the intrinsic viscosities of thyroglobulin at *p*H 8·0 and *p*H 3·5 was less than that at *p*H 8·0 and *p*H 1·5 (Fig. 1). Precipitation work to be described elsewhere showed the *p*H 3·5 preparation to be 50–60 per cent denatured, whereas *p*H 1·5 thyroglobulin was completely denatured. The latter result could account for the great difference in viscosity of the *p*H 1·5 material from either of the two preparations.

At *p*H 8·0, thyroglobulin showed three components, whereas two boundaries were evident at lower *p*H (Fig. 2). Molecular weight calculations using sedimentation values and viscosities of the different thyroglobulin preparations were made[3b]. The partial specific volume for thyroglobulin was taken as

Thyroglobulin in 0·1 *M* phosphate buffer, *p*H 8·0. (*B*) Duration of spin, 47 min. Upper, thyroglobulin in 0·25 *M* acetate buffer, *p*H 3·5; lower, thyroglobulin in 0·1 *M* hydrochloric acid–potassium chloride buffer, *p*H 1·5

0·714 (ref. 1). Table 1 summarizes the different results obtained, together with the relative concentrations of each component derived from the areas under the peaks. At *p*H 3·5, a species, which was approximately one-half the molecular weight of the $S_{20,w}$ = 14·7 component of *p*H 8·0 thyroglobulin, was formed. The same finding was apparent at *p*H 1·5. The relative concentrations of the sedimentable components at *p*H 3·5 and *p*H 1·5 are approximately the same, so the $S_{20,w}$ = 8·0 or 8·3 components could not be denatured forms of thyroglobulin. It could be more plausible to explain these forms as arising from a dissociation phenomenon analogous to that observed by Edelhoch[1].

Evidence of Thyroid Protease Action

A MATERIAL rich in proteolytic activity against hæmoglobin can be obtained from thyroid glands by ammonium sulphate precipitation followed by methanol–sodium chloride fractionation[4]. However, this preparation is relatively ineffective against thyroglobulin[5]. Although an alternative method of thyroid protease preparation by acetone fractionation[7] provides substantial improvements in the yield and purity of the proteolytic activity against hæmoglobin, the activity against thyroglobulin is not affected, nor does treatment of the substrate by urea improve this activity. In previous work, the methods used for following proteolysis were those aimed at the detection of small peptide fragments or the known iodinated thyroid hormones. If, however, the main action of thyroid protease is to hydrolyse only a few crucial bonds in thyroglobulin, thus enabling other enzymes to act, then it is rather easy to see why these methods depict the enzyme as relatively ineffective against thyroglobulin. This report provides evidence for the premise.

Sheep thyroglobulin, prepared according to the method in ref. 2, was dissolved in 1 per cent concentration in either 0·1 *M* phosphate buffer at *p*H 7·0 or in 0·25 *M* acetate buffer at *p*H 3·5. The upper curve in Fig. 3*A* and the lower curve in Fig. 3*C* show the ultracentrifugal patterns of each thyroglobulin preparation. Thyroid protease showed one peak in either buffer (Fig. 3*A*, lower and Fig. 3*C*, upper).

After 2- and 6-hr. incubation at 37° C. in the Dubnoff shaker, aliquots of the *p*H 3·5 thyroglobulin and *p*H 7 thyroglobulin, each incubated with thyroid protease, were removed for examination in the Spinco model *E* ultracentrifuge and for viscosity investigation using standard procedures[3a]. Fig. 3*B* shows no change in the ultracentrifugal patterns of the *p*H 7·0 thyroglobulin hydrolysate. However, marked alterations were seen in *p*H 3·5 thyroglobulin (Fig. 3, *D* and *E*).

Molecular weights can be determined from the sedimentation constants and viscosities[3b]. The

viscosity measurements in this work were made on heterogeneous preparations, hence the calculated viscosity was the sum of viscosities of each component in the preparation. It was felt that this method, while not precisely accurate for molecular weight determinations, could give an approximation of what happened to the major component of the thyroglobulin preparation. As Table 2 shows, when no action of the enzyme was evident, the calculated molecular weight of the main thyroglobulin peak remained within the value of the control. The value of 0·714 was used as the partial specific volume of thyroglobulin[1]. Table 2 shows more than 50 per cent of *p*H 3·5 thyroglobulin reduced in a 2-hr. incubation to a component having a molecular weight less than one-tenth of the control. A further degradation occurred with progression of the incubation period.

With these observations and other work, it is postulated that thyroid protease exerts a 'priming' action on thyroglobulin by breaking it down into small polypeptide fragments. The formation afterwards of the thyroid hormones could take place as the result of such processes as the action of thyroid peptidases, action of serum peptidases, or reversal of biosynthetic pathways.

I wish to express my gratitude to Drs. M. J. Spiro and J. B. Stanbury for their advice and helpful suggestions.

CORRELATION BETWEEN GROWTH-RATE OF THE SUCKLING OF VARIOUS SPECIES AND THE PERCENTAGE OF TOTAL CALORIES FROM PROTEIN IN THE MILK

By DR. F. W. BERNHART

Wyeth Institute for Medical Research, Radnor, Pennsylvania

BUNGE[1] proposed that there is a direct correlation between the growth-rate of the sucklings of several species (expressed as the number of days required for doubling the birth-weight) and the percentages of protein and ash in the fluid milk.

As a normal animal ingests only the amount of food necessary to satisfy the caloric requirement, maximal growth will occur only if this intake contains an adequate amount of protein (and all other nutritionally essential materials as well) for metabolic needs and for formation of new tissue. Powers[3] pointed out that as the requirement for calories determines intake of food, the percentage of total calories derived from protein is a better measure of the protein content of milk.

Using the percentage of total calories from protein as the criterion of protein content of milk, Powers[3] concluded that there is no correlation between the rate of growth of the suckling and the protein content. Brodie[4] concluded "that the situation is too complex for simple generalization although speed of growth, composition and physiological age are important factors in determining the evolutionary trend of milk composition".

Available data indicate that there is an inverse linear correlation between the percentage of total

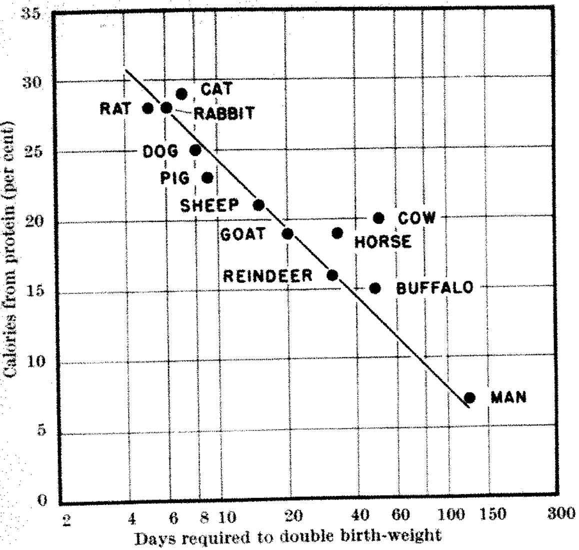

Fig. 1. The correlation between the percentage of total calories from protein and the number of days required to double the birth-weight. The formula of the line fitted by method of least squares is $y = 41 - 16{\cdot}5 \log x$ (data for cow not included)

calories supplied by protein in the milk and the logarithm of the number of days required to double the birth-weight of several species. The results for all species for which presumably reliable estimates of both variables have been found are listed in Table 1. A plot based on these results is shown in Fig. 1.

Early growth tends to follow the first-order reaction-rate[4]:

$$\frac{dW}{dt} = KW$$

where W is weight; t is time; K is first-order reaction-constant from which the following expression may be derived:

$$K = \frac{0{\cdot}693}{t_2}$$

where t_2 is days required to double the birth-weight.

The correlation between the log of K versus percentage calories from protein is positive and linear.

The caloric contents were calculated, using the factors 9, 4 and 4 cal./gm. for fat, protein and carbohydrate. Values for the time required for doubling the birth-weight were selected from work in which, so far as possible, optimal conditions were maintained. The values listed are considered to be the average for different varieties of a species.

The results indicate that the same relationship between protein supplied by the milk and rate of growth of various species is also true in man. The cow, however, appears to be an exception. In this species the percentage calories supplied by the protein of the milk is considerably greater than would be expected from the growth-rate. An excess of milk protein in relation to growth-rate is present, to a lesser extent, in the horse and buffalo. These three animals are herbivores with relatively slow growth-rates. A possible explanation for the excess of protein in their milks is that the food of the sucklings is also forage, and the higher protein content of the milk compensates for the lower protein content of the forage.

The elephant, not listed in Table 1, is of particular interest. Elephant milk has about the same protein content as human milk (7 per cent of calories)[3], but no exact information on rate of growth could be found. The Indian elephant is weaned at 4–5 years, puberty occurs at 14–15 years in the male and first calving at 15–16 years; full maturity is reached at the age of 40 and the life-span ranges up to 75 years. These similarities to man indicate that the elephant and human beings may have, during early life, similar rates of growth, predictable from the similar low protein content of the milk of these species.

Table 1. PERCENTAGE OF CALORIES FROM PROTEIN IN THE MILK AND GROWTH-RATE (EXPRESSED AS DAYS REQUIRED TO DOUBLE BIRTH-WEIGHT) OF VARIOUS SPECIES

Species	Total calories from protein (per cent)	Refs.	Days to double birth-weight	Refs.
Man	7	11	125	6, 7
Buffalo	15	12	48	17
Reindeer	16	12	31	3
Horse	19	12	33	18
Goat	19	11	20	12, 3
Cow	20	11	50	28
Sheep	21	12	15	19, 3
Pig	23	13	9	20
Dog	25	14	8	28, 2
Rabbit	28	15	6	21
Rat	28	16	5	8
Cat	29	15, 2	7	22, 4

According to Brodie[4] the speed of growth is an important factor in determining the evolutionary trend of milk composition rather than milk composition having a role in determining the growth-rate. That the protein content of milk is not the factor limiting the rate of growth was pointed out by Minot[5], as increasing the protein intake above that supplied by the milk has not been shown to cause an increase in the rate of growth. The only results have been obtained from human studies. The growth-curves of breast-fed infants during the period required to double the birth-weight[6] were practically identical to those obtained in an earlier investigation at the same location with a large number of infants preponderantly fed cow's milk formulæ supplying 2–3 times as much protein[7].

A rough approximation of the amount of protein supplied by milk in relation to needs of the suckling may be made by comparing the protein intake from milk with the protein requirement after weaning. The results in Table 2 indicate that the protein requirement of the weanlings of various species for optimal growth is about half the amount of protein supplied by the milk. A larger amount of protein supplied by milk, as compared with the dietary requirement after weaning, is necessary for the rapid rate of growth after birth in comparison with the markedly slower growth-rate after weaning[4]. In man, requirement for protein per kgm. body-weight after birth is 1·9 times the requirement at 6 months[9].

Table 2. COMPARISON OF THE PERCENTAGE OF CALORIES FROM PROTEIN IN MILKS WITH REQUIREMENT FOR OPTIMAL GROWTH AFTER WEANING

Species	Calories from protein (per cent)		Ratio	Source of protein	Refs.
	In milk (1)	Post-weaning require-ment (2)			
Man	7·2	4·4	0·61	Cow's milk	9
Pig	23	12	0·52	Cow's milk	23
Dog	25	17	0·68	Corn, yeast, casein	24
Rat	28	15	0·54	Casein plus 0·5 per cent methionine	25
Cat	29	19	0·66	Casein	26

These results indicate that generally the milks of the various species supply an amount of protein adequate for maximal growth but not much more.

The advantage of the evolutionary development of a milk composition which supplies enough protein for maximal growth of the offspring is evident. Nature's conservatism in limiting protein to the suckling is undoubtedly of benefit to the mother. The strain of lactation would be increased if excess protein were excreted in the milk, in view of the mother's limited stores of body protein and possible difficulties in obtaining an adequate protein intake to maintain positive nitrogen balance.

It is also possible that an adequate, though limited, protein intake may be of benefit to the offspring as well. Holt[10] has reviewed the recent literature on the effects of various protein-levels in the diet on body composition, enzyme-levels, effects of stresses, diseases and starvation and incidence of tumours. In several of these investigations diets supplying low or normal protein intake were found to be advantageous in comparison with those with higher amounts.

At the present time there is disagreement about the most advantageous level of protein intake of artificially fed infants. Gyorgy[27], a proponent of lower protein intakes for artificially fed infants, has used teleology as an argument; that is, there is a nutritional advantage associated with the low protein content of human milk because of purpose in Nature.

This teleological argument is strengthened by the present work, which supports the point of view that the same relationship between protein intake and growth-rate found in most other species is also true in man.

TREATMENT OF HOPS (*HUMULUS LUPULUS*, L.) WITH GIBBERELLIC ACID

Effect of Spraying with Gibberellic Acid on Yield and Composition

NASH AND MULLANEY[1] have described trials in which hops were treated with various concentrations of gibberellic acid. The maximum effect was observed when the plants were sprayed at the time of burr formation and accordingly a large-scale trial was carried out in which the Australian commercial variety Pride of Ringwood was sprayed with 12·5 p.p.m. of the potassium salt of gibberellic acid at this time. At harvest, the yield of the treated hops was 39 per cent higher than that of the controls, but on analysis the treated hops contained only 1·8 per cent of α-acid on which the brewing value largely depends, as compared with 10·2 per cent of α-acids in the controls. The overall yield of useful material for brewing was therefore depressed considerably by the treatment. It appeared possible, however, that the treated hops might have appeared ripe prematurely and that if they had been left in the field longer the resin content might have risen to the same level as that found in the controls.

The results reported here are of a similar field trial conducted under English conditions, using the variety Bullion (*Q*43). Samples were taken throughout the ripening period until resin synthesis was demonstrably complete. Twenty-five hills of two-year-old plants of the variety Bullion grown in the Withersdane Garden, Wye College, were sprayed with a solution containing 12·5 p.p.m. of the potassium salt of gibberellic acid on July 19, 1960, at which time the majority of the stigmas of the female plants were about $\frac{1}{8}$ in. long. Twenty-five similar hills served as the controls. Within a week of application the treated plants showed differences from the controls in their growth and development. The new leaves were noticeably paler green and the laterals were longer with more extended internodes. Furthermore, the cones in the treated plants developed more rapidly than those of the untreated plants, with the result that, 15 days after spraying, the dry weight per 100 cones of the treated hops was 4·32 gm. compared with 1·40 gm. with the controls. A summary of the analytical data obtained with these and later samples are given in Table 1. With the immature samples the normal methods of analysis for α-acid were insufficiently sensitive, but when the resin obtained from these hops was examined by ion-exchange chromatography[2] the presence of α-acids in the treated hops and their absence in the controls was clearly demonstrated. At the time of the second sampling (August 17, 1960), the visual difference between the treated and control samples had largely disappeared, but the treated hops still contained more resin and α-acids than the controls. Both samples contained a trace of steam-volatile oil, though when this was examined by gas chromatography none of the components of the essential oil of mature hops could be detected. At the third sampling (August 31, 1960), resin synthesis in both treated and control samples appeared to be complete. On the other hand, the essential oils continued to be synthesized until harvest (September 29, 1960), a point which has not emerged from earlier investigations.

Table 1. ANALYSIS OF CONTROL HOPS AND THOSE SPRAYED WITH GIBBERELLIC ACID (AFTER KILNING)

Sample	Date of sampling	Days after spraying	Nature of sample	Total soft resin (per cent) (ref. 3)	α-Acid/polarimetric (per cent) (ref. 3)	Essential oil (per cent)
1	4.8.60	16	Control	1·3	0·00*	—
			Treated	1·7	0·05*	—
2	17·8·60	29	Control	1·3	0·04*	0·03
			Treated	3·3	0·27*	0·025
3	31.8.60	43	Control	13·8	6·7	0·42
			Treated	13·8	6·7	0·38
4	14.9.60	57	Control	13·3	5·4	0·65
			Treated	13·5	5·7	0·78
5	29·9·60	72	Control	13·6	6·3	0·86
			Treated	13·7	6·5	1·00

* By ion-exchange chromatography (ref. 2).

At harvest the control hops yielded 3·25 lb. of green hops per bine while the treated hops only gave 2·59 lb. of green hops per bine. Both groups contained the same percentage of dry matter (23·3 per cent), soft resin, and α-acid. These results are therefore in complete contrast to those of Nash and Mullaney. The differences in the results of the Australian and British investigations cannot as yet be accounted for with certainty, but may be due to varietal or perhaps climatic conditions. For example, during the period of this trial 10·22 in. of rain were recorded at Wye, compared with a 25-year average value for this period of 7·27 in. The hours of sunshine per day and the mean temperature were also lower than the 25-year average. In view of these circumstances it is desirable to repeat the trial during at least one further year and the results of the more extended investigations will be reported in full detail later. Nevertheless, the present results are of interest in establishing that the earlier Australian results do not necessarily reflect a general effect.

We thank Dr. A. H. Cook, Dr. H. S. Darling and Dr. G. Harris for their interest and advice in these investigations.

Effect on Growth and Development

GIBBERELLIC acid has been shown to increase markedly the rate of elongation and the length of internodes in many plants[1]. Several workers have shown that juvenile characteristics, notably leaf form, can be prolonged or induced using this substance[2–4].

The rate of elongation of the hop during the vegetative or spring phase of growth is very considerable for a temperate plant. Shoots appear above ground in April and may reach a height of five metres by the end of the first week in June. Mature plants can sustain daily elongation rates of 8–10 cm. during this period. The leaf-form of the earliest leaves is entire; those developing later show a transition from the simple to the three, five or seven lobed 'adult' form. In the course of a series of experiments it was decided to examine in the summer of 1958 the effect of gibberellic acid on shoot-growth and leaf-form during the vegetative phase.

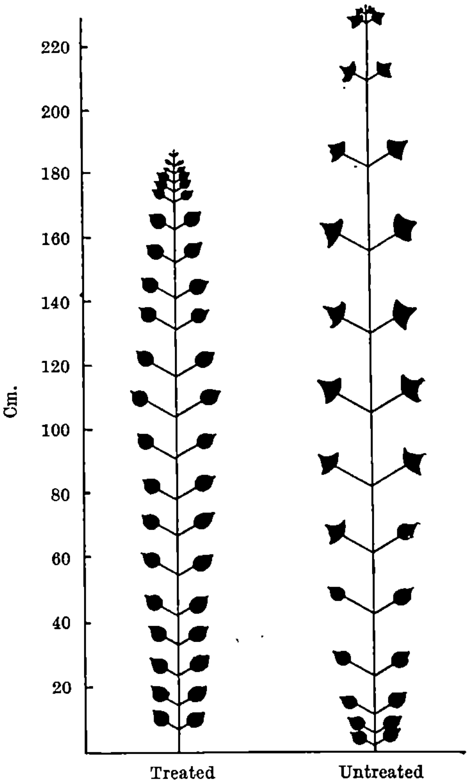

Fig. 1. Leaf-form and internode-length

Vernalized[5] seedlings were grown in a cool glasshouse. Treatment began immediately after the cotyledons had expanded. Gibberellic acid was applied, using a hand spray, at 5-day intervals at strengths of 1, 5 and 10 p.p.m. The treated seedlings elongated more rapidly initially, and the first two or three internodes were considerably longer than those of the controls. Thereafter the maximum internode-length of the treated plants did not exceed 14 cm. whereas the control plants developed successively longer internodes which reached a maximum length of 26 cm. when the experiment was concluded. The rate of elongation declined in the treated plants so that their mean height was significantly less than the untreated plants at the end of the experiment. The number of nodes developed by the treated plants was, however, a third greater than the controls. The treated leaves remained entire whereas all the untreated plants developed the typical lobed leaves before the ninth pair (Fig. 1).

It seems possible that the natural rate of elongation of the hop shoot, after the first few internodes have developed, represents the maximum capacity of cell elongation in this plant. In this case gibberellic acid may have had a secondary effect in speeding up the rate of meristematic development shown by the greater number of nodes which the treated plants developed.

The treated plants had a larger total leaf area than the controls, but their leaves were chlorotic, being very pale green in colour. This may have indicated a lower photosynthetic capacity than the controls where the leaves were normal in colour, and may have been responsible for the gradual decline in the rate of elongation of the treated plants.

From a fundamental point of view the present results are of some interest, but from a practical point of view it has yet to be shown that gibberellic acid will be of use in the growth of this crop.

CHROMATOGRAPHIC INVESTIGATION OF THE METHYL ALCOHOL/CHLOROFORM-SOLUBLE CONSTITUENTS OF HONEYBEE LARVAL FOODS

By N. G. PATEL, M. H. HAYDAK and R. LOVELL

University of Minnesota, St. Paul, 1

THE lipid content of the food given to the queen larvæ (royal jelly: RJ) remains fairly constant during the time of the larval growth, while that of the food given to 3–5-day-old larvæ (modified drone and worker jelly: MDJ and MWJ respectively) decreases considerably in comparison with the food of 1–2-day-old larvæ (drone and worker jelly: DJ and WJ)[1,2]. Since the nutrition plays a decisive part in the differentiation of caste in the honeybee[3], an investigation of any change[4] or heterogeneity[5] in the constituents of the larval food is important.

The larval foods were collected and stored as reported earlier[4]. In order to correlate the components contributed to the food by the glands, the hypopharyngeal, thoracic and mandibular glands were dissected from the freshly emerged bees and the 6-day post-emergence nurse-bees and placed in methyl alcohol/chloroform (1 : 2) and stored at – 40° C. with other larval food until further use.

For the analysis, each sample of the larval food was thawed and stirred, and a 1-gm. aliquot withdrawn for extraction. The extraction was carried out at room temperature in an Erlenmeyer flask with 20 ml. methyl alcohol/chloroform (1 : 2) mixture as the solvent and 20 min. stirring with the magnetic stirrer. The homogenate was filtered through a sintered-glass filter under suction. The process was repeated once with 10 ml. of the solvent mixture to assure complete extraction. Assays showed that close to 22 per cent of the material was extracted. The extraction of the glands was done by homogenizing them in the same solvent with the Potter–Elvehjem homogenizer and filtering through a 0·45μ pore-size 'Millipore' filter disk.

The separation of the constituents was done by ascending chromatography using thin films of silicic acid on glass plates[6]. 50 μl. of the filtrate samples were analysed by using different proportions of methyl alcohol/chloroform. 29 per cent methyl alcohol in chloroform gave the best separation. After the solvent front had migrated about 7 in., the plates were removed and dried at room temperature. Fluorescent spots were observed under 3660 Å. and 2537 Å. wave-length ultra-violet light. Following the ultra-violet observation, the replicated plates were treated respectively with different colour reagents, which included *p*-anisidine, ninhydrin, iron chloride, iodine vapour and concentrated sulphuric acid at 130° C. for half an hour. A composite representation of the various treatments is shown in Fig. 1.

It is seen from Fig. 1 that there is considerable complexity of constituents in normal and modified jellies of all castes. Apparently there is no difference in the long-wave (faint spots) ultra-violet fluorescent spots of young and old royal jellies (YRJ and ORJ). MDJ and MWJ are similar, but have one component less than DJ and WJ. YRJ and ORJ have one fluorescent component more than DJ and WJ with similar migration pattern, while the pattern of the MDJ and MWJ is different. These fluorescent spots could be of pteridine type as indicated by Remboldt and Hanser[7]. The one spot migrating to the top has originated in the mandibular glands of the nurse-bee and may be 10-OH-Δ-2-decenoic acid[8]. With the short ultra-violet light (dark spots), an additional difference is seen in MDJ and MWJ as compared with other jellies.

The colour reactions also illustrate the complexity involved and indicate from which gland a particular compound is contributed to different jellies. A positive reaction with iron chloride (a green spot turning yellow) is exhibited by YRJ, ORJ, MDJ, MWJ and extracts from the hypopharyngeal glands of nurse-bees; it is not present in DJ and WJ. Ninhy-

Upper and lower photographs correspond to upper and lower photographs of (*b*). Other abbreviations as in Fig. 1

drin- and *p*-anisidine-positive spots have similar migration patterns. The slower positive ninhydrin spots apparently originate in the hypopharyngeal glands of nurse-bees, while the migration of the *p*-anisidine-positive components from thoracic, mandibular and hypopharyngeal glands coincides with those fast-migrating spots of the jellies. The hypopharyngeal glands seem to contribute a larger share of *p*-anisidine-positive compounds. A preliminary paper-chromatographic separation shows that all the jellies have glucose and fructose, and sucrose is present in YRJ, ORJ, DJ and WJ while absent in MDJ and MWJ. On the other hand, MDJ and MWJ have maltose, which is absent in the rest of the samples.

The iodine vapour treatment indicating unsaturation exhibits four spots with a similar pattern in YRJ, ORJ, DJ and WJ, while there are only two components in MDJ and MWJ. These chromatograms were sprayed with concentrated sulphuric acid and heated to char the organic components (Fig. 2*a*). This treatment revealed other differences, but the resolution was not satisfactory. Better resolution was obtained by re-chromatography. Plates chromatographed with 29 per cent methyl alcohol in chloroform were divided into three as shown in Fig. 2*a*. The eluates from the top, middle and bottom sections were re-chromatographed in 5, 22 and 40 per cent methyl alcohol in chloroform, respectively. The top division did not reveal any significant qualitative differences as compared with the rest, which are shown in Fig. 2*b*. Quantitatively, the charring (Fig. 2*a*) in the top spots of YRJ, ORJ, DJ and WJ was at least twice that in MDJ and JWJ. This spot, as indicated earlier, may be 10-OH-Δ-2-decenoic acid. The concentration of re-spotted eluates in Fig. 2*b* at the point of origin was three times greater than that used earlier. The charring of the redeveloped plates was followed after the iodine treatment (Fig. 2*c*), so that the unsaturation could be compared with it. It is evident that the general pattern of the YRJ and ORJ remains the same and is not comparable with that of other jellies; however, there are some spots which are qualitatively similar though with quantitative differences. Unsaturation indicated by iodine vapour does not strictly correlate with the charring, particularly the slowly migrating components. This might be due to low concentrations of the components present and the amounts of reagents used to give coloured spots for visual observations.

A comparative study of the qualitative and quantitative changes of the components in relation to the age and different castes is of profound interest and importance. As is shown in this preliminary work, the biochemistry of the larval foods is quite complex. This complexity in turn is passed over to the nutritional phase and the phenomenon of dimorphism. The isolation, further characterization and incorporation of these biochemicals in a well-planned nutritional research investigation may help us to understand and control the formation of the queen and the workers.

NERVOUS AND BIOCHEMICAL DISTURBANCES FOLLOWING HEXACHLOROBENZENE INTOXICATION

By Dr. F. De MATTEIS*, B. E. PRIOR and Prof. C. RIMINGTON, F.R.S.
Department of Chemical Pathology, University College Medical School, University Street, London, W.C.1

OUTBREAKS of cutaneous porphyria, involving several thousand cases, have occurred in districts of south-eastern Turkey since 1956[1]. Affected individuals, predominantly children, are said to exhibit photosensitivity, hepatomegaly and porphyrinuria but no abdominal or neurological symptoms. Poisoning by hexachlorobenzene, C_6Cl_6, introduced in bread made from dressed wheat intended for sowing, has been suspected as the cause of these disturbances. Ockner and Schmid[2] have confirmed such suspicions by administering hexachlorobenzene to adult male rats and observing neurological symptoms and increased urinary excretion of porphyrins and porphyrin precursors. Hepatomegaly with degeneration of liver cells was common in porphyric rats. There was no decrease in liver catalase or alteration in blood porphyrins or hæmoglobin, and no red fluorescence in the bone marrow *post mortem*, although the cortex of the long bones exhibited fluorescence. Of 33 rats started on the experimental diet, 13 died within the first month exhibiting terminal tremor, ataxia, weakness and paralysis but no major disturbance of porphyrin metabolism, while the remainder showed porphyrinuria, porphobilinogenuria and increased excretion of δ-aminolævulic acid after 2–8 weeks.

---

* British Council Scholar from the Institute of Clinical Medicine, University of Bari, Italy.

We have studied hexachlorobenzene intoxication in rabbits, guinea pigs, male and female rats and mice and have observed interesting differences in pattern of symptoms and chemical disturbances shown by each species. In addition, we have studied the susceptibility of the fœtal and new-born rat to poisoning from the hexachlorobenzene-fed mother. The biochemical picture seen in the rabbit most nearly resembles that described in man, and for this reason we have carried out most of our experiments with these animals. They are more rapidly affected by the poison and develop uroporphyrinuria, in contrast to the more usual coproporphyrinuria of the rat; disturbances of the central nervous system are relatively slight. Parke and Williams[3] found a single oral dose of hexachlorobenzene remained largely unchanged in the gut of rabbits after 5 days. There was no significant urinary or pulmonary excretion of metabolites. They found, however, increased urinary excretion of glucuronic acid, mainly in the free form. Cameron *et al.*[4] found subcutaneous injection of a dose as large as 0·5 gm. to rats produced no toxic effects.

Rabbits. Females (1·5–2·5 kgm.) were fed a diet prepared by powdering rabbit pellets ('Diet *S.G.* 1', Joseph Rank, Ltd.) incorporating 0·5 per cent of hexachlorobenzene, moistening with water, and then drying in shallow pans at about 60° C. Urine and fæces were collected separately. Five to six days were allowed for the establishment of basal excretion before institution of the drug. Pooled 2-day urines were analysed for uroporphyrin[5], coproporphyrin[6], porphobilinogen, δ-aminolævulic acid[7] and glucuronic acid[8]. Blood hæmoglobin and body-weight were recorded at the commencement and the end of the experiment. Tissue porphyrins[9] were determined after death. Organs were examined under ultra-violet light and those found to be fluorescent were prepared for ultra-violet microscopy. Paper chromatography was used for identification of the abnormal urinary constituents.

The general picture observed was development of increased urinary porphyrin, which was mainly uroporphyrin, after administration of the drug for about six weeks. This uroporphyrinuria became progressively more severe and was accompanied by a rise in coproporphyrin but a decline in glucuronic acid excretion, while there was no significant change in the levels of δ-aminolævulic acid or porphobilinogen. When determining the latter in the eluate from the 'Dowex 2' column[7], it was noticed that development of colour continued, reaching its maximum after about 6 hr. Chromatographic examination showed the substance responsible for this extra colour production to be not porphobilinogen but another Ehrlich reactor, possibly pyrrole-2-carboxylic acid. Rabbit urine is alkaline, and such a substance might be derived secondarily from a precursor (Gottschalk[10]). The identity of these materials and the relation they bear to administration either of the drug or of the heated diet (see later) are under investigation. The animals lost weight and suffered from oliguria and constipation, with diminished intake of food and water; their hæmoglobin remained unchanged. Unless killed earlier, they died after 8–12 weeks, having shown for the last week or so neurological symptoms in the form of tremor and paresis.

Out of 4 animals, 2 showed marked disturbance of porphyrin metabolism, another less marked, and another only slight disturbance. Nevertheless, all exhibited the same final neurological picture. Some of the biochemical changes in a typical example are shown in Fig. 1. Post-mortem examination revealed intense red fluorescence in ultra-violet light of the liver and adjacent tissue and of the bones, particularly of the metaphyseal region of the long bones but also along the diaphyphyseal insertion of the muscles. This picture of porphyrin distribution was confirmed by ultra-violet microscopy of suitably prepared transverse sections. There was no fluorescence in the bone marrow. The liver showed fatty change and patchy necrosis of varying degrees of severity. Under ultra-violet light, porphyrin was visible mainly in the centrilobular region. The degree of porphyrin fluorescence was related to the intensity of the porphyrin excretion during life. Necrosis, degeneration and focal calcification were seen in a few areas in muscles. No evident abnormality was found in the central or peripheral nervous systems in spite of the neurological symptoms shown by all animals.

Chemical analysis of organs showed massive quantities of a uro-type porphyrin in the liver, with only slight increase in the coproporphyrin and protoporphyrin fractions. Uro-type porphyrin was also detected in appreciable amounts in the serum and other organs examined. The qualitative reaction for porphobilinogen in the liver was negative. Paper chromatography of the uro fraction from the liver

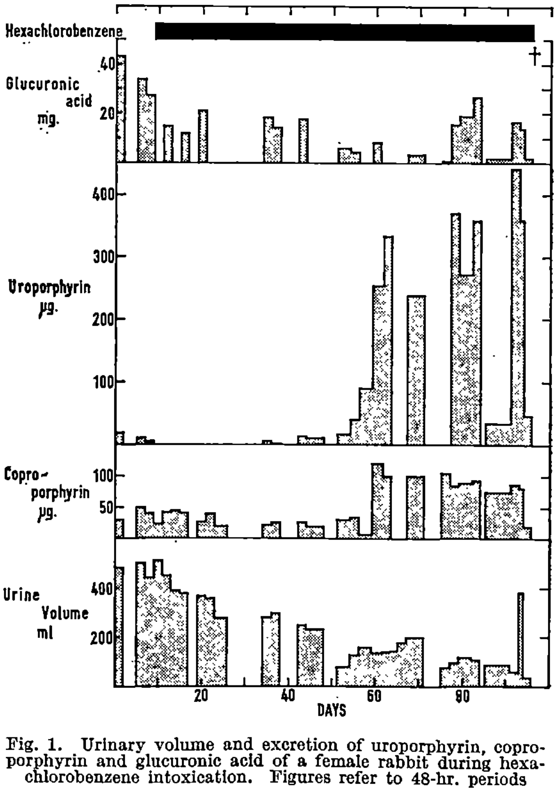

Fig. 1. Urinary volume and excretion of uroporphyrin, coproporphyrin and glucuronic acid of a female rabbit during hexachlorobenzene intoxication. Figures refer to 48-hr. periods

showed that it was mainly uroporphyrin III with some pseudo-uroporphyrin[11], whereas the uro fraction from the urine was predominantly pseudo-uroporphyrin. The urinary copro fraction was found to contain some coproporphyrin III together with pseudo-uroporphyrin and other porphyrins with chromatographic behaviour similar to hexa- and penta-carboxylic porphyrins.

Guinea pigs and mice. The level of dosage of hexachlorobenzene and means of administration in the diet were the same as for rabbits. These two species were found to be remarkably susceptible to hexachlorobenzene poisoning and to develop within 8–10 days very marked neurological symptoms. In guinea pigs, these took the form of continuous, rather coarse tremor of the extremities, interrupted by occasional clonic convulsions. There was also weakness, which was often more pronounced along one side of the body, so that the animals had difficulty in standing, could not right themselves if placed on the back and when moving in the cage they leaned against the wall for support. Mice exhibited a finer tremor involving the whole body, including head and tail. In place of convulsions, clonic contractions affecting mainly the hind limbs took place, so that the animals jumped like frogs. In both species there was a marked hyper-excitability, the symptoms being intensified by touch. If the drug was withdrawn within 24 hr. of development of nervous symptoms, recovery took place, but not otherwise. Death was preceded by progressive extreme weakness. All attempts to influence the symptoms described above by means of drugs such as hyoscine, chlorpromazine, phenylhydantoin, pyridoxine and asparagine were unsuccessful. Careful examination of the nervous systems of one guinea pig which died with typical tremor failed to reveal any structural changes.

Chemical analysis of the urine showed an early, marked increase in a δ-aminolævulic acid-like substance (see later), no significant changes being observed in porphobilinogen and porphyrin excretion except for a slight preterminal increase in coproporphyrin. Blood ammonia determinations were carried out in guinea pigs in view of the known ability of hexachlorobenzene to cause liver injury and the association of tremor and raised blood-ammonia in human cases of severe hepatic damage. All four guinea pigs so studied had ammonia values two to three times greater than their three normal controls. Liver histology, on the contrary, showed little evidence of damage apart from some fatty change.

Rats. The picture of hexachlorobenzene intoxication in rats resembles that in rabbits in its main features, with marked disturbance of porphyrin metabolism and only slight terminal neurological symptoms. The metabolic changes differed, however, in some important details. We observed a gradual increase in coproporphyrin and later of uroporphyrin with a terminal excretion of porphobilinogen which may be considerable. The identity of the latter was established by paper chromatography[12]; no chromogen reacting slowly with Ehrlich reagent was detected. The urinary coproporphyrin was identified chromatographically as mainly coproporphyrin III, only traces, if any, of the porphyrins intermediate between this and uroporphyrin being found. In addition to the picture described above, a prompt and sustained rise was seen in excretion of glucuronic acid and of a δ-aminolævulic acid-like material. The identity of the latter is still under investigation. Coincident with the terminal rise in porphobilinogen, there is an increased excretion of true δ-aminolævulic acid. Excretion of the δ-aminolævulic acid-like material and the rise in urinary glucuronic acid were both found to be associated with consumption of a diet prepared by heating and are therefore not relevant to intoxication by hexachlorobenzene.

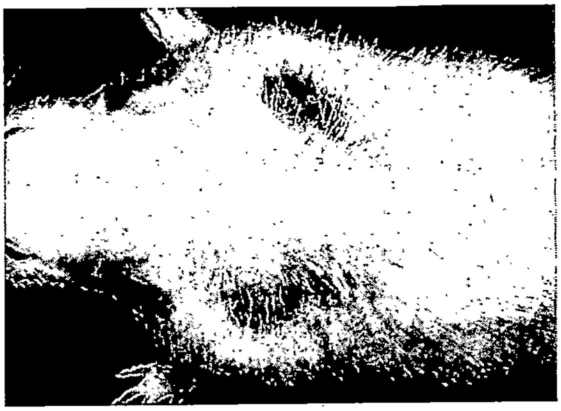

Fig. 2. Dermal lesions shown by a rat receiving hexachlorobenzene

In addition to the general picture of terminal neurological disturbance, some rats showed, at an earlier stage, cutaneous lesions in the form of depilated sores with hæmorrhagic crusts. These appeared before the animals developed porphyrinuria and were often symmetrically placed near the shoulder (Fig. 2). The animals showed signs of itching; hence scratching may have played some part in the development of these lesions. Quantitative tests for photosensitivity with a monochromator[13] were kindly carried out for us by Dr. H. A. Magnus but proved completely negative. Tests repeated during the phase of increased urinary porphyrin excretion failed to produce reaction at either 380, 400 or 420 mμ.

Two pregnant female rats were also given hexachlorobenzene in their food. One died, but the other was delivered normally and reared the young until they died with convulsions after 7–8 days. She was then given 3 normal week-old baby rats to foster. These died 3–4 days later with convulsions. The mother died 4 weeks later showing the usual picture. It would appear that the baby rat is particularly susceptible to the nervous effects of this poison.

The hexachlorobenzene used for the above experiments was the technical chemical, since examination had shown it to be free from less-highly chlorinated hydrocarbons. To eliminate the possibility that the observed toxic effects could be due to an impurity, some mice and rats were given pure hexachlorobenzene prepared as a standard for the estimation of halogen (British Drug Houses, Ltd.). These animals reacted in exactly the same way and after the same time as did those receiving the technical-grade product.

Discussion

Experiments with these four species of animal have confirmed the toxicity of hexachlorobenzene. Whereas cutaneous lesions dominate the picture in man and nervous symptoms are absent, our experimental animals have all shown striking neurological symptoms which were not associated with pathological change histologically evident in the central or peripheral nervous systems. It would therefore seem that these symptoms have a biochemical origin, and in this connexion it is interesting that affected guinea pigs had raised blood ammonia.

The nervous symptoms do not appear to be closely related to disturbed porphyrin metabolism, since in susceptible species they develop relatively rapidly and before pigment metabolism becomes markedly affected. Porphyrinuria must be looked upon as a chronic effect of continued hexachlorobenzene intoxication, not seen in those animals dying earlier from nervous complications.

The experiments on rats confirm Ockner and Schmid's[2] report of increased urinary porphyrin and porphobilinogen excretion after prolonged administration of hexachlorobenzene. A rise in true δ-aminolævulic acid usually occurs coincidently with the rise in porphobilinogen towards the end of the experiment. The cutaneous lesions we have seen in this species suggest chronic dermal irritation rather than photosensitivity.

The disturbance caused by the drug in the porphyrin metabolism of rabbits was more marked than in the rat and also resembled the human condition more nearly. As in clinical material from Turkey, uroporphyrin was the predominant urinary porphyrin and porphobilinogen was consistently absent. Post-mortem analyses revealed massive deposits of uroporphyrin III in the liver, appreciable uroporphyrin in the plasma and several other organs, including bones, but no significant increase of porphyrin in the bone marrow. The porphyrin in the urine was mainly of uro-type, including pseudo-uroporphyrin; chromatography of the copro fraction revealed that even here pseudo-uroporphyrin and hexa- and penta-carboxylic porphyrins were strongly represented. Such a distribution within the body strongly suggests a porphyria of hepatic type with possible interference to the uroporphyrinogen decarboxylating mechanism.

Increase in the excretion of glucuronic acid was not observed in the experiments on rabbits, although this has been reported by Parke and Williams[3] to follow administration of hexachlorobenzene. Cutaneous lesions were not seen; our rabbits were housed in diffuse light, and no tests for photosensitivity were carried out.

Many problems remain to be solved in connexion with hexachlorobenzene intoxication. Investigation of the pathogenesis of the porphyrin dyscrasia in different animals should help to throw light on the condition caused by this drug in man. The somewhat surprising findings of neurological disturbances arising in animals, which might well be due to the relatively high dosage-level employed, are of intrinsic interest and deserve further investigation.

Dr. W. R. Lee, of the Institute of Orthopædics, kindly prepared and examined by ultra-violet microscopy the sections of porphyrin-containing bone from our rabbits. We wish to thank Dr. J. Smith for advice on the histological material and Mr. R. Belcher and Mrs. A. Latter for technical assistance. Dr. M. D. Turner of the Royal Free Hospital kindly carried out the determinations of blood ammonia.

MECHANISM OF SENSITIVITY TO HYDROSTATIC PRESSURE IN THE PRAWN, *PALAEMONETES VARIANS* LEACH

By PETER S. B. DIGBY
Department of Biology, St. Thomas's Hospital Medical School, London, S.E.1

MANY marine animals exhibit sensitivity to hydrostatic pressures of less than 100 lb./in.^{2}; some being sensitive to pressures equivalent to a depth of only a few centimetres of water. An increase of pressure causes active swimming upwards, a decrease usually causes passive sinking, but some forms swim actively downwards[1-3]. The mechanism has so far remained obscure.

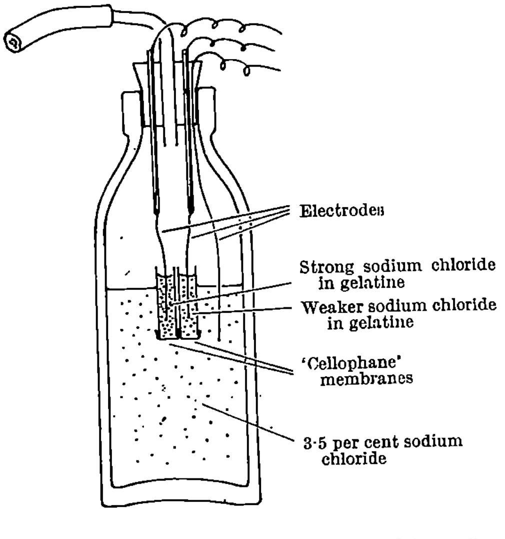
The prawn *Palaemonetes varians* is sensitive to pressure, as are a number of Crustacea, and if confined in a bottle it will swim to the surface when a pressure of 40 lb./in.^{2} is applied and will sink again when it is released. The surface potential on a prawn, together with the electrode potential, investigated crudely by passing one copper electrode into the abdomen and placing the other in the water beside it, was found to be 50 mV. or more negative to the surrounding salt water. When the electrodes were connected through a 50-ohm galvanometer, the flow of current proved to be sensitive to pressure; although it declined rapidly, repeatedly increasing the pressure to 40 lb./in.^{2} for a few seconds, caused corresponding increases of current by up to 20 per cent. Investigation of the electric field in the water surrounding a prawn free in a shallow dish, showed that the ventral surface is the more negative. Vital staining with nile blue showed that the negative parts stain deeply, namely, the gills and the part of the abdomen bathed by the water coming from them. The potentials arise partly from differences of pH in the water bathing the two electrodes.

Since different parts of the prawn differ in potential, and small currents flow, it seemed possible that sensitivity to pressure might reside in the properties of a very thin film of gas produced electrolytically on some surface. To see if this might be feasible, a model was constructed in the form of a diffusion cell, consisting of a 6·0-cm. length of 7 mm. glass tubing with one end open and the other closed by a 'Cellophane' membrane. The tube was filled with

10 per cent gelatine and strong salt solution, and was supported vertically in the pressure bottle half-full of 3·5 per cent salt solution with the 'Cellophane' membrane below the surface and the open end above. One copper electrode was passed into the gelatine, the other into the surrounding salt solution. A diffusion potential was set up, the inside of the cell being negative to the salt solution as in the prawn. Single cells did not prove very sensitive to pressure at first, although they became so on standing for a day. When charged by a slightly larger outside potential, a freshly made cell immediately became sensitive to pressure.

As the prawn has different potentials across different parts of its integument, it may be regarded as two cells connected in parallel, one charging the other. In a further model therefore, two cells similar to that discussed here were mounted side by side in the same bottle (Fig. 1), producing potentials of −60 mV. and −20 mV., respectively, relative to the solution by virtue of their different internal salt concentrations. On connecting the two central electrodes through a 50-ohm galvanometer, the current recorded at once became sensitive to pressure, being 5–10 per cent greater at 40 lb./in.^{2}. This arrangement (Fig. 2) represents the free prawn, where the inner parts of the body surface of differing potentials are connected electrically by body tissues, the outer by sea-water. The current between these cells and the surrounding solution, an arrangement representing the prawn mounted on one electrode, is also sensitive to pressure. Experiments showed that the sensitive element is the weaker cell, charged by the stronger. The electric currents are very small and no gas can be seen until some hours have elapsed. Gas is, however, produced electrolytically in small amounts down to zero potential on a metallic electrode[4], and we may conclude that such a thin gaseous film forms immediately on connecting up. The layer may be only a few angstrom units thick, insufficient to produce obvious optical effects, but nevertheless having the compressibility of a gas and producing electrical effects which vary with pressure.

The outstanding question is whether such a gas film can be formed on the surface of an animal.



Electrodes
Strong sodium chloride in gelatine
Weaker sodium chloride in gelatine
'Cellophane' membranes
3·5 per cent sodium chloride

Fig. 1. Pressure bottle showing arrangement of two cells containing different concentrations of sodium chloride in 10 per cent gelatine

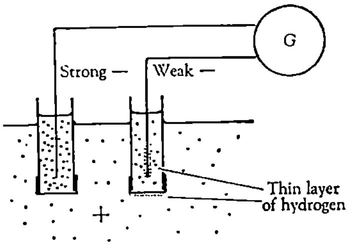


Fig. 2. Pressure-sensitive system, corresponding to arrangement in shrimp swimming free in water, when internal tissues take the place of the galvanometer

In order that gas shall be formed electrolytically, electron conductance must occur, as in the metallic electrode. That this is possible in the prawn may be demonstrated by applying a potential of 100 V. across the surface in distilled water, when hydrogen is freely evolved from much of the integument and, if a trace of copper sulphate is added, metallic copper is deposited. The hydrogen or copper ions are discharged by electrons passing through semi-conducting molecules or structures in sufficient numbers to produce visible amounts of discharge products at the high voltage. By the same procedure, hydrogen may be evolved from and copper deposited on a membrane of 'Cellophane' stained with methylene blue or coated with beeswax. At the lower voltages prevailing normally in the living animal, a correspondingly smaller number of ions will be discharged.

That such electrolytically produced gas layers occur in the prawn is suggested by the increase of sensitivity which follows the addition of salt and acid to the surrounding water. Further evidence is provided by experiments with surface-active substances that ionize to give charged complexes. Thus small amounts of 'Cetavlon' cetrimide B.P., which gives a negative bromide ion and a positive complex, completely destroyed the pressure-sensitivity of both the prawns and the diffusion cells. Small amounts of 'Teepol', which yields a negative complex, did not destroy this sensitivity in either, but sometimes enhanced it. As the positive complex which destroys the pressure sensitivity will migrate to the negative surface and there alter the charge, it is the most negative surface that is liable to blocking with 'Cetavlon' and is therefore first the gills. It is the outer surface which is coated because, after abolishing by 'Cetavlon' treatment, the sensitivity could be regained by immersing in sodium bicarbonate solution for some minutes to remove the substance, rinsing in acid water and transferring to fresh saline. The thin layers of hydrogen will, however, tend to be formed electrolytically on the outer surface wherever electrons can leak through the semiconducting structures in the integument under the influence of the normal potential drop across the surface.

Natural substances poison the surface, for prawns lose their sensitivity to pressure when crowded in a vessel with no seaweed and regain it when kept in a vessel containing seaweed. When lost, the sensitivity can also be restored by bicarbonate and acid rinses. Indeed the latter treatment, followed by the addition of a little salt, was found to induce or enhance sensitivity to pressure in the freshwater *Daphnia pulex*, which when newly caught showed only a trace of this reaction.

The widespread nature of charged surfaces in living biological material renders it likely that a capacity for pressure-sensitivity, based on the properties of a very thin film or perhaps partly adsorbed layer of electrolytically produced gas, may develop in a variety of situations where free hydrogen or hydroxyl ions are available against the surface of a charged membrane containing semi-conducting substances which allow a leakage of electrons.

Details of this work, which is continuing, will be published elsewhere. Certain initial experiments were carried out at the Kristineberg Zoological Station, Sweden; my thanks are due to the Director and his staff.

LOCATION OF POLYGENES

By Prof. J. M. THODAY

Department of Genetics, Milton Road, Cambridge

QUANTITATIVE genetics, hitherto, has been a subject distinct from Mendelian genetics in the sense that the specific genes segregating in any particular situation have not been handled as separate entities.

The first step of classical genetics is to identify the genes concerned as entities separable in heredity and to locate them on linkage maps so that thereafter they may be handled unequivocally in experiment. Our ability to do this depends on the classification of phenotypes into discrete groups, and the characteristic statistical techniques involved are those based on the χ^2 test of goodness of fit.

In the study of quantitative characters, on the other hand, the continuous nature of the relevant variation naturally leads to analyses of variance and, hence, to a biometrical approach. Using this approach has given us great insight into the problems, and we know that continuous and discontinuous heritable variation have in common the properties of segregation, dominance, interaction and linkage. It is established beyond doubt that the genes of biometrical genetics and the major genes of Mendelian genetics are subject to the same rules of inheritance for the same reasons; they are chromosomal[1].

Though the techniques of biometrical genetics are most elegant and informative, the resulting understanding of quantitative variation lacks the precision it would be given if we were to locate relevant genes with greater accuracy in linkage maps. Only when this has been done will we be able to look at a genic difference that has only been detected by its effect on a quantitative character and discover what it does and how it contributes to phenotypic variation.

The nature of the variation makes this difficult. In the best-studied examples, it is clear that the variation arises from genetic variation at a number of loci, and that the contribution of any locus to phenotypic variance is sufficiently small relative to that of the other loci and that arising from environmental causes and accidents of development to make the effects of that locus difficult to handle independently. To some extent this has affected our attitude to continuous variation, so that even those whose specific study is continuous variation, whether from a pure or applied point of view, seem rather often to act as if they thought that experimental control of the separate loci were in principle impossible. Statements occur in the literature such as "it is impossible to show the presence of these groups of linked polygenes by normal Mendelian methods"[2] or " . . . non-identifiability of genotypes and dependence on environment . . . have led to the development of a branch of genetics to which the name biometrical genetics is applied"[3]. Such statements may, however qualified by their authors, lead readily to a general feeling that any attempt to locate the genes of quantitative genetics would be defeated before it began. Those who are not specifically concerned with understanding quantitative genetics, but are interested in a character from some other point of view, may well be forgiven if they often seem to regard the demonstration that the character is inherited 'polygenically' as an end to investigation rather than a beginning.

Now it is clear that there is nothing in principle, though it may be difficult or laborious in practice, to prevent us from handling the genes concerned with quantitative variables by more or less classical genetic methods. Biometrical genetics is based on the fact that discontinuous variates, if there are enough of them, may be treated as if they were continuous variates, and it is implicit that the underlying genetic discontinuities are there to be uncovered. In fact, Johannson did just this by progeny testing and demonstrating that a number of different classes of inbred lines could be established from a strain varying in seed weight. Sax used a different approach when he used a marker to classify chromosomes and hence to detect linkage between major genes and quantitative genes[1], and the elegant experiments of Breese and Mather[4] go still further in this direction by splitting a chromosome into a number of component pieces and showing each of them to contain some of the relevant factors. But what has not been done is to exploit the possibilities fully by combining these two approaches.

My colleagues and I have had some success at this in the past few years, and it seems worth while to describe the basis of our techniques.

These depend upon the following simple principles: Suppose that we have found that a chromosome gives a higher value of a metric character than that given by a homologous chromosome marked with the recessive major genes a and b. We then test-cross individuals possessing this chromosome to the homozygous ab/ab stock, pick up equal numbers of the $++/ab$, ab/ab, $a+/ab$ and $+b/ab$ progeny and assay them for the metric character.

Let genes increasing the value of the metric character be H and their alleles L.

Suppose there is only one HL locus. Then the F_1 individuals test-crossed are either $H++/Lab$, $++H/abL$ or $+H+/aLb$ depending on the position of the HL locus in relation to the marker loci. Assuming the locus to be near enough to the markers for linkage to be detected, then the first two arrangements will give results such that one recombinant marker class is similar to one of the parental classes, and the other recombinant marker class is similar to the other parental class. The $+H+/aLb$ arrangement will give different results. Ignoring double crossing-over, the $++$ class will all be H, the ab class will all be L. A proportion of the $+b$ class will be H, the rest L, and reciprocal proportions of the $a+$ class will be H and L. The parental classes will therefore have distinct means but, since they are homogeneous, low variances. The recombination classes, on the other hand, will, as they are heterogeneous, have relatively high variances, their means being intermediate between the parental classes.

In investigating a particular chromosome, our first step is to search for a pair of markers which produce such results, that is to say, are outside the HL genes we wish to locate.

Now such results do not indicate there is only one locus. Suppose there are two, both between the marker loci, and suppose them to be in coupling. Then the F_1 individuals test-crossed are $+HH+/aLLb$. Again ignoring double crossing-over, the $++$ parental class of progeny are all HH, and the ab class all LL. The parental classes are homogeneous and different in mean. The recombination class $+b$ may be either HH, HL or LL, and the recombination class $a+$ either HH, LH or LL. Again the recombination classes are heterogeneous, and will have intermediate means and high variances.

The essential problem is to distinguish between the one locus and the two locus results. This is relatively easy. With one locus each marker recombinant class falls into two classes; they are either H or L. With two loci each marker recombinant class comprises three classes, HH, HL or LH, and LL. If, then, we progeny-test adequately a sufficient number of each marker recombinant class to determine how many classes it contains, we can determine whether one or two (or more) loci must be invoked to explain the difference in which we are interested. If we proceed far enough, we shall be able to assess not only the number but also the frequencies of the classes and hence obtain map-distances.

The investigation of a particular quantitative genetic difference thus proceeds in the following way: We first investigate which chromosomes are effective, by test-crossing with a stock in which, if possible, each chromosome of the haploid set is marked, and in the same breeding programme separate from one another the chromosomes of the genome in which we are interested. We then test the effective chromosome against a number of marked stocks in order to determine which are suitable markers. We then obtain adequate numbers of recombinant chromosomes and classify them by progeny-testing to see whether they fall into two or into three classes.

The feeling that the genes of quantitative genetics may not be readily located has been strengthened by the knowledge that much of the relevant genetic variation is cryptic. It is to this that Kempthorne referred in using the phrase "unidentifiability of genotypes" in the quotation referred to here. Such a situation occurs when two genomes, or more particularly two homologous chromosomes, differ genetically, but not in their phenotypic effects, because the relevant genes are in the repulsion phase. But this does not make it impossible to handle the genes concerned in breeding experiments. Consider again two loci: the heterozygote is HL/LH and will produce HH and LL gametes the presence of which can be detected in the progeny of such heterozygotes, for they will have a higher variance than the progeny of individuals homozygous for either chromosome. It was in fact just such a test that led Gibson and Thoday[5,6] to discover and locate the relevant loci in the population in which they were interested.

More sophisticated techniques can be derived easily to break down more complex situations so that they can be treated in this simple way, to deal with homozygous as well as heterozygous effects of the chromosomes being analysed, and to re-synthesize the analysed chromosomes to check conclusions. When it proves necessary to use markers themselves affecting the character concerned or marker stocks themselves possessing inconvenient combinations of relevant polygenes, the elegant breeding system of Breese and Mather[4] can readily be modified to include the only essential of our method, sufficient progeny-testing of sufficient recombinant chromosomes of each marker class to determine how many classes they fall into in terms of their effect on the quantitative character.

The main practical limitation of the technique seems to be the availability of suitable markers, and the time that can be given to the considerable work involved. No doubt there is also a lower limit of genetic differences that would make genes of slight effect difficult to isolate, because there is a limit to the reduction of other sources of variance that can be achieved, though inbreeding of the marker stocks can help. The technique may therefore lead to isolation of non-random samples of polygenes of larger than average effect, can only tell us what is the minimum number of loci we must invoke, and may not tell us how complex the loci identified are. Whether these will prove serious limitations we do not know.

We have, in fact, had considerable success using such techniques in the analysis of sternopleural chæta number loci in *Drosophila melanogaster*. We have explained a major response to artificial selection in a line 'dp1', of Thoday and Boam[7] in terms of two loci at about 28 and 32 centi-Morgans on the third linkage group. Wolstenholme has analysed the high-chæta number flies of the polymorphic population 'D+' of Thoday and Boam[8] and found them to be distinguished by two factors at about 49 and 51 centi-Morgans on the third linkage map. Using these and also other techniques made possible by lethality interactions of the genes concerned, Gibson has located two factors from the low-chæta number flies of the 'D+' population at about 27 and 47 centi-Morgans on the second linkage group. In the latter case we have for the first time shown how the relevant loci occur in the population from which the selection line is derived[6]. We are at present analysing second chromosomes derived from the populations of Millicent and Thoday[9,10] and have roughly located two factors in these at about 47 and 64 centi-Morgans.

None of these investigations has yet been pushed to the extent where we have tried to determine the relative frequency of the different classes, and in only one have we good evidence that two and not more than two loci are concerned. Nevertheless, we have gone far enough in each investigation to satisfy ourselves that the location of the genes is not too difficult, and are able to place them in the second and third linkage maps as shown in Fig. 1.

The precision of these locations is not great. We know 1 and 2 to be separate, and that both are between *h* and *eyg*; we know 3 and 4 to be about 20

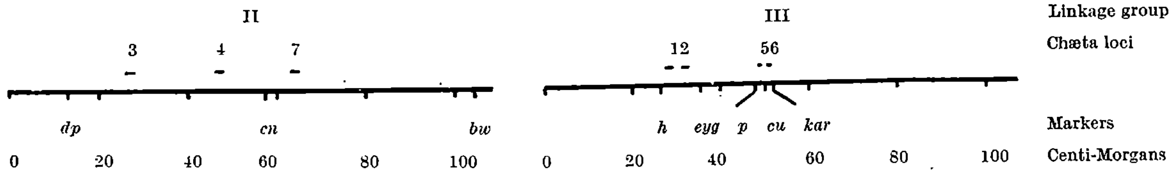

Fig. 1

centi-Morgans apart, that 3 is some 10 centi-Morgans to the right of *dp*, and 4 and some 8 centi-Morgans to the left of *cn*. We know 7 is to the right of *cn* and a long way from *bw*. We know that 5 is between *p* and *cu* and that 6 is to the right of *cu* and to the left of *kar*. The precision of the locations, and our knowledge of the chromosomes containing the relevant alleles are, however, sufficient for us to test future chromosomes against these and so identify new loci relatively easily.

Furthermore, we are now in a position to handle these loci in breeding experiments with sufficient precision to permit us to investigate their developmental effects. This should permit us to discover whether the different genes affect chæta number in different or similar ways. It may also permit us to discover other attributes of the various genotypes which are not so dependent on environmental and other sources of variance, and hence with some loci at least to classify genotypes directly from observations of phenotype that give discontinuity. It remains to be seen whether this will prove possible and if so whether it is only possible in special cases.

The present account of the principles of our methods is published with the view of encouraging others to approach their own problems in quantitative genetics with the possibility in mind of locating polygenes. An extensive attack on quantitative genetics made from this point of view as well as the biometric approach should be a great help in answering questions concerning the nature of polygenes, the randomness of their distribution in chromosomes, their relation to major genes and to heterochromatin, and whether or not they are a homogeneous or heterogeneous class of genes. At the same time, such an approach should bring new understanding of the consequences of artificial selection, and of the genetic architecture of natural and artificial populations.

PREPARATION OF MITOCHONDRIA FROM THE PEEL OF APPLES

By Dr. J. D. JONES and Dr. A. C. HULME
Ditton Laboratory (Agricultural Research Council), Larkfield, Maidstone, Kent

TWO main difficulties in the isolation of active mitochondria from apple fruits are the low and well-buffered *p*H of the sap and the presence in the tissues of inhibitors, the chief of which has been thought to be of a polyphenolic nature, probably an oxidized *o*-dihydroxyphenol[1,2]. The successful isolation of mitochondria from the apple[3-5] has been achieved in recent years by the use of alkaline extraction media to neutralize the acid of the sap and by the use of peeled fruit, since the peel contains a relatively large amount of phenolic substances. The addition of ascorbic acid to the extraction medium has been advocated to keep these substances in the reduced form during the isolation procedures.

We are particularly interested in the metabolism of the peel of apples. Apart from the high concentration of phenolic substances in the peel[6] and their alleged effect on mitochondrial activity, peel tissue is difficult to disintegrate because of its leathery texture; satisfactory comminution cannot be achieved by grinding with sand in a mortar or by the use of a Waring blendor.

Grassman *et al.*[7] have shown that a polyamide material known as 'Perlon' or 'Ultramid' has a strong affinity for phenolic compounds, and Novikoff[8] has shown that the incorporation of polyvinylpyrrolidone (PVP) in the extraction medium preserves the morphological and biochemical integrity of mitochondria. Several workers[9-11] have advocated the use of PVP in the preparation of animal mitochondria, but its use has not been reported for mitochondria from plant sources.

A method has been developed for the preparation of mitochondria from the peel of Cox's Orange Pippin apples which incorporates the use of both 'Ultramid' and PVP and in which the tissue is disintegrated in a specially designed roller mill made in stainless steel. Briefly, the method is as follows: Peel (25 gm.) is added to a sucrose buffer solution (0·4 *M* sucrose) containing phosphate, citrate[12] ethylenediaminetetraacetic acid (EDTA) and 5 per cent PVP (molecular weight 25,000, pharmaceutical grade). The tissue is vacuum-infiltrated with the solution by placing in a vacuum desiccator for 10 min. and then releasing the vacuum. It is then passed through the diagonally serrated rollers of the mill and the ground material mixed thoroughly with the original solution to which has been added 5 gm. of 'Ultramid'. The tissue is then squeezed through two layers of muslin and the mitochondria separated from the filtrate according to the usual procedures for plant mitochondria. All preparative procedures are performed at 1° C. The particles are finally suspended in a solution of sucrose (0·3 *M*) and phosphate (0·2 *M*, *p*H 7·5) containing a small amount of adenosine triphosphate and adenosine monophosphate. These suspensions are used for assays of enzyme activity; uptake of oxygen and

outputs of carbon dioxide are measured by the standard Warburg manometric methods at 25° C. and at *p*H 7·5.

In presenting a summary of preliminary results, it is felt that the special features of the method may be of importance, not only to studies of the mitochondria of fruits, but also to studies of plant mitochondria and other enzyme systems in general. The use of PVP may also have a wider importance in relation to any large molecules precipitated and 'inactivated' by 'tannins'.

More than 100 active preparations have been studied which stain with janus green and satisfy the criteria for Krebs cycle activity of mitochondria[13], including oxidative phosphorylation. Pyruvate is readily oxidized in presence of 'sparking' amounts of malic acid. The best preparations have succinic dehydrogenase activity higher than that of most other preparations of plant mitochondria (Table 1).

The effect of the incorporation of PVP in the extracting medium varies with *p*H; and the uptake of oxygen and output of carbon dioxide to added succinate of preparations made with PVP over the range of *p*H 6·0–10·0 are shown in Fig. 1. It appears that these mitochondria are like those from other plant sources in that their activity is greatest when extraction is done at *p*H 7·0–7·5. Whereas in the absence of PVP the addition of ascorbic acid reduces darkening in the extracting medium, it does not enhance the activity of the particles prepared with or without PVP. The incorporation of polyamide ('Ultramid') in the extracting medium does not enhance the activity of the particles, but it has the useful physical effect of coagulating a gel, which is otherwise troublesome during the first centrifugation.

At this stage the role of PVP must be largely a matter for speculation. It does not appear to be acting merely to protect (by complex formation) the mitochondria from inactivation by polyphenols. A range of phenolic compounds (chlorogenic acid, caffeic acid, phloridzin and *o*-coumaric acid) added to the Warburg flasks at a concentration of 0·001 *M* causes at the most a 10 per cent diminution in the activity of succinic oxidase; gallic acid at the same concentration brings about a 25 per cent inhibition, and catechol and tannic acid are the only compounds tried which cause complete inhibition. Tannic acid inhibition is partially reversed by adding PVP to Warburg contents. Even a fairly concentrated extract of the 'phenolic fraction' from the leaves of Cox's Orange Pippin apples causes only 35 per cent inhibition. Apart from catechol and tannic acid all these compounds produce a slight initial diminution in the output of carbon dioxide when succinic acid (0·02 *M*) is added. At higher concentrations (0·02 *M*) chlorogenic acid causes an uptake of oxygen about equal to succinate, and when the two are added together the uptake of oxygen is 85–90 per cent of that expected from simple additions of the separate uptakes, while the output of carbon dioxide due to succinate is unaffected.

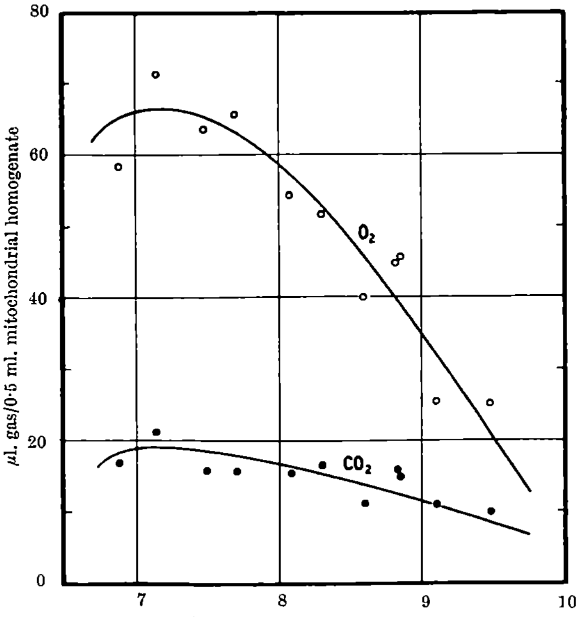

Fig. 1. Uptake of oxygen and output of carbon dioxide in the presence of 0·02 *M* succinate of mitochondria from apple peel prepared at various values of *p*H in the presence of PVP

Striking differences appear in the effect of the *p*H of the extracting medium, in the presence or absence of PVP, on the subsequent activity of the particles if the results are expressed on a nitrogen basis as compared with a given quantity of mitochondrial homogenate. Our methods are now sufficiently standardized and reproducible to justify this.

Results for preparations from comparable tissue are shown in Table 2. The rise in activity between *p*H 7·9 and 9·5 (extracting medium) without PVP, expressed on a nitrogen basis, agrees with the results of Lieberman[5] for mitochondria from apple pulp,

Table 2. μL. OXYGEN-UPTAKE (ACTIVITY) PRODUCED BY APPLE PEEL MITOCHONDRIA PREPARED IN VARIOUS WAYS
(Average rate per hr. over first 2 hr. in Warburg)

Without PVP			With PVP		
Final *p*H of extract used	Activity per unit N of preparation	Activity per 0·5 ml. of preparation	Final *p*H of extract used	Activity per unit N of preparation	Activity per 0·5 ml. of preparation
6·6	80	23	6·8	295	57
7·5	85	36	7·5	365	70
7·9	73	32	8·1	330	55
9·0	145	26	8·9	255	38
9·5	210	38	9·5	162	25

but this rise is almost entirely a reflexion of the fall of the nitrogen content of the preparation over this range of pH. The nitrogen content of the particles prepared with PVP varies between 0·112 and 0·230 mgm./0·5 ml. of homogenate whereas without PVP the range is 0·177–0·500 mgm. nitrogen with all the values below 0·300 mgm. being above pH 8·0.

It is suggested: (1) The relatively high nitrogen content of particles prepared without PVP at values of pH between 6 and 8 is a result of the formation of insoluble complexes between non-mitochondrial protein and phenolic substances in the peel, these complexes being spun down with the mitochondria. (2) At pH values above 8–9 these complexes are soluble and are not therefore spun down with the particles. (3) PVP forms soluble complexes with the phenolic substances which cannot therefore precipitate non-mitochondrial protein to contaminate the mitochondria. Suggestions (1) and (3) are supported by the results of Guttram and Higuchi[17], who showed that phenols form complexes with PVP, and by Swain (private communication), who showed recently that tannin extracts form inactive complexes with certain enzymes, the inactivation being reversed by PVP and some other polymers.

Until the uncertainty as to the true mitochondrial-nitrogen content of our preparations has been cleared up, we prefer to express our results in terms of the amount of mitochondrial homogenate (Fig. 1).

The general higher activity of preparations obtained with PVP, regardless of nitrogen content, may also be due to the removal by the PVP of inhibitors, whether they be of a phenolic nature or not.

Full details of this work will be published elsewhere.

AN AUSTRALOPITHECINE SCOOP MADE FROM A RIGHT AUSTRALOPITHECINE UPPER ARM BONE

By Prof. RAYMOND A. DART

University of the Witwatersrand, Johannesburg

TWO years ago, I compared[1a] several antelope cannon-bone scoops from the basal grey breccia at the Makapansgat Limeworks site with a late Victorian sheep cannon-bone scoop (or apple-corer) made by a Ledbury lad in Herefordshire in the last decade of last century. Another scoop from the same grey breccia has now been found, but it was made from the distal end of an australopithecine humerus and by the different technique (see Fig. 1, extreme right specimen) of spiral splitting. For comparison with this australopithecine humeral scoop, the first figure includes a cast of the Ledbury apple-corer, a rather ornate apple-corer that came from the sale of an old Natal settler's effects and an imitation of the Ledbury specimen made from an equally slender antelope cannon-bone by Mr. Ronald Klomfass, technical assistant in the Anatomy Department of the University of the Witwatersrand. When found in a Johannesburg curio shop, the purpose of the Natal apple-scoop was unknown to its purchaser, Mr. J. C. Cohn; he found its counterpart eventually in a cannon-bone scoop in the collection of the Pitt-Rivers Museum at Oxford. Later, when he learned about the repetitive occurrence of antelope cannon-bone scoops in the Makapansgat basal grey breccia, he kindly gave me this Natal specimen. Presumably, it had been brought from England some time last century, possibly from Oxfordshire, by the original settler (whose name unfortunately is unknown).

Since the original announcement in *Nature*, much corroborative evidence has been forthcoming (ref. 2 and through newspaper reports as well as correspondence) about cannon-bone scoops. Spatulæ of this sort were in such general demand by our edentulous forefathers for pulping crisp fruits and eating other pulped foods that they were freely reproduced in ivory (or silver) for folk more well-to-do. These imitations were often divided into screw-threaded halves so that the scoop-half fitted into the handle-half for easy transport[2b]. The geographical and temporal gap between Victorian England and australopithecine South Africa also has been bridged considerably by the series of bone spatulæ (see Fig. 2) to which Dr. A. J. Arkell has kindly directed my attention[3]. Incidentally, this series shows that cannon-bone scoops were even more prized by ancient Egyptians than by recent Europeans. The left-hand specimen is "certainly fossil" according to Dr. Kenneth Oakley and possibly Palæolithic; the second is typical of several excavated by Dr. Arkell himself from the Neolithic site at Shaheinab near Khartoum in the Sudan. The other two (Nos. 3 and 4) were found among the grave furniture of two Egyptian tombs of the third millennium B.C.

The Victorian cannon-bone scoops were made with the aid of a pen-knife; the ivory imitations were turned on a lathe, as the Natal specimen may also have been. Mr. Trevor Jones of Salisbury, Southern Rhodesia, aided me in discovering the bone-on-bone

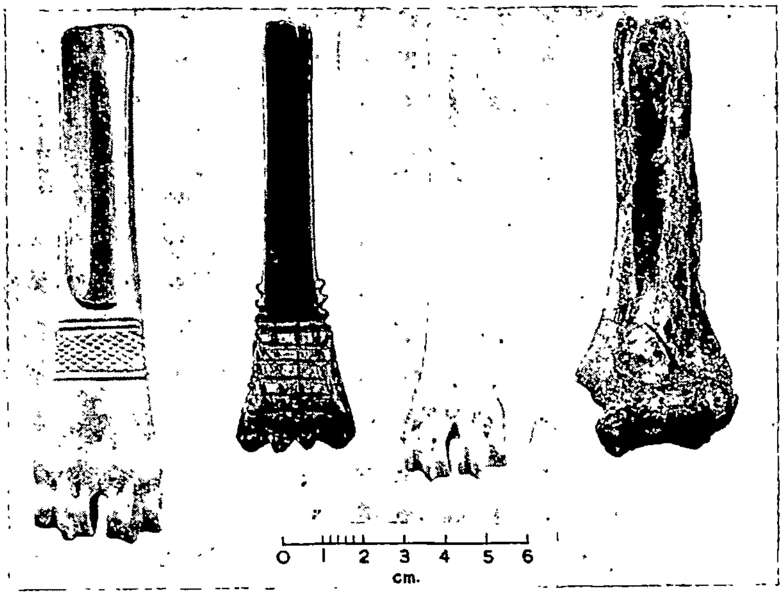

Fig. 1. An australopithecine and some recent bone scoops. The australopithecine humeral bone scoop from the Makapansgat grey breccia (extreme right) compared with —from left to right—a cast of the Ledbury bone scoop, the ornate Natal settler's specimen and an antelope cannon-bone scoop of similar calibre made recently in Johannesburg. Note the long spiral fracture of the australopithecine specimen and the abraded edges of the bone due to wear especially around its blade-like end

pounding or battering technique that produced the first australopithecine specimens described, and the precision labour it entailed[1].

This new australopithecine humeral scoop resembles more closely technically Dr. Arkell's cannon-bone spatulæ from the Nile Valley. It was prepared by the crack-and-twist technique, which was discovered by Mr. James W. Kitching and has been described elsewhere[4]. A single, well-controlled impact enough only to crack the bone enables one to twist the ends apart between the hands contrariwise.

Hazardous as it may appear to speculate from line-drawings how these Nile Valley bone spatulæ were prepared—especially when their surfaces have probably been smoothed by use, some possibly even on grindstones—the irregularity in the curvature of the broken bone surface of the Neolithic specimen (Fig. 2, No. 2) shows that it, at least, was first fractured by the same kind of crack-and-twist technique as *Australopithecus* employed at Makapansgat.

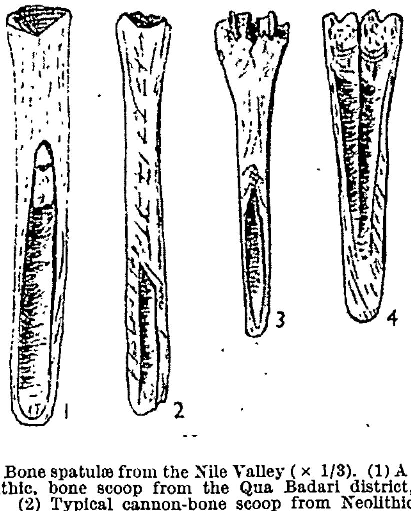

Fig. 2. Bone spatulæ from the Nile Valley (× 1/3). (1) A fossil (?) Palæolithic, bone scoop from the Qua Badari district, Middle Egypt. (2) Typical cannon-bone scoop from Neolithic site of Shaheinab, near Khartoum. (3) and (4) Cannon-bone scoops found among the grave furniture of two Egyptian tombs of the third millennium B.C.

This crack-and-twist technique must also have been used by *Sinanthropus* in China, to produce the spiral humeral fractures of antelope and other bovid bones at Choukoutien, by Kalkbank man in South Africa and by Mesolithic man in Portugal[4c,5]. So this early human bone-tool-making technique became dispersed over the entire Old World mass and has persisted from australopithecine times, when it was apparently invented, until very recently indeed.

This particular australopithecine scoop prepared from an australopithecine humerus also supports the inference made from the bowl-shaped condition in which the first female australopithecine occiput was found that *Australopithecus prometheus* was cannibalistic. The fact that it is the distal portion of a right humerus suggests that already some concept may have germinated in its fabricator's mentality that by its use he embodied some of his defunct opponent's vitality.

The value of the cannon-bone scoops or spatulæ lies not merely in the age-long persistence of the tradition they display but also in their overcoming the dental infirmities of mankind, for which they compensated. They explain the dental knives and scrapers and the food-pulping pestles and mortars of bone as well as the skull-bowls that accompany them. Upon these osteodontokeratic utensils domestic human family life was being built untold thousands of years before stone tools were adapted to its improvement. Von Koenigswald[6] has traced the human use of skull-bowls from *Sinanthropus* to Ngandong and recent times.

The interest of this australopithecine humeral scoop, like that of the australopithecine occipital skull-bowl, lies in the antiquity they reveal for human veneration of human bones above all other bones.

Acknowledgment is made to the South African Council for Scientific and Industrial Research, the Council of the University of the Witwatersrand, the Wenner-Gren Foundation and especially to the Wilkie Foundation of Des Plaines, Illinois, U.S.A., for the financial assistance which has maintained the field and laboratory work that has led to this and previous discoveries.

Absorption Spectrum of γ-Irradiated Lead Silicate Glass

In an earlier communication[1] it was stated that the absorption spectrum of γ-irradiated lead silicate glass showed three absorption bands at 1·7 eV., 2·3 eV. and 3·3 eV. respectively. The separation of the spectral curve into these bands was obtained by assuming that the peak at 3·3 eV. was uninfluenced by the presence of any other bands. The points in the vicinity of this peak were used to estimate the first Gaussian and the other bands were obtained by successive subtraction.

As the amount of available data increased, further work employing different methods has been done in order to confirm this separation, making only the assumption that the spectral absorption curve consists of a small number of Gaussian-shaped components.

This problem is well suited to solution by means of an electronic digital computer and a programme was written using the equation:

$$y = \Sigma A_i \exp B_i (x - c_i)^2$$

where A_i corresponds to the peak height of the absorption band at a wave-length of $1/c_i$, B_i is a function of the half-peak width of this band, and x is the reciprocal of the wave-length at the point considered. By a process of successive iteration it was found that the full spectral absorption curve in the region 350–1,000 mμ could be accurately represented as the sum of two Gaussian absorption bands with maxima at 2·54 eV. and 3·36 eV.

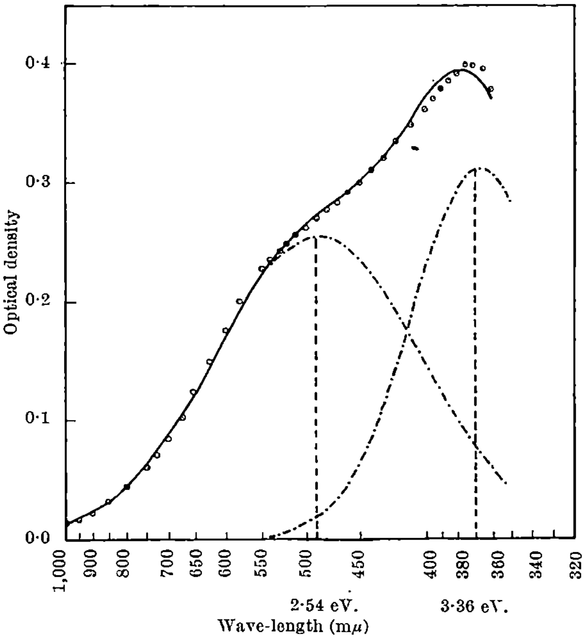

Fig. 1. Spectral absorption curve for γ-irradiated lead silicate glass. Dose, $3 \cdot 2 \times 10^4$ rads after 455 min.

The result shown in Fig. 1 is typical of many results so obtained, and it can be seen that there is now no evidence for an absorption band at 1·7 eV., but that there is considerable interaction between the two bands at their peak wave-lengths. The encircled points are the measured values and the full-line is the sum of the two Gaussian bands obtained by computation.

Rotational Analysis of Absorption Bands of Lead Monoxide

The low-lying states of N_2 and of CO arise from electron configurations[1] which may be written:

$$\pi^4\sigma^2,\ X^1\Sigma^+ \qquad (1)$$

$$\pi^4\sigma\pi,\ {}^3\Pi_r,\ {}^1\Pi \qquad (2)$$

$$\pi^3\sigma^2\pi,\ {}^1\Sigma^+,\ {}^1\Sigma^-,\ {}^3\Sigma^+,\ {}^3\Sigma^-,\ {}^1\Delta,\ {}^3\Delta \qquad (3)$$

In the group of molecules from CO to PbTe, the allowed absorption bands of longest wave-length may then be expected to be ${}^1\Sigma^+, {}^1\pi - X^1\Sigma^+$. This is found to be the case, for example, in SiS, where the systems $D^1\Pi - X^1\Sigma^+$ and $E^1\Sigma^+ - X^1\Sigma^+$ appear readily in absorption[2,3]. In addition, evidence about some other predicted states, notably $e^3\Sigma^-$, $I^1\Sigma^-$ and (?) ${}^1\Delta$, has been obtained from work[4,5] on the perturbations in $D^1\Pi$. In SiO, GeO and SnO there is no further strong absorption[6] until wave-lengths considerably shorter than those corresponding to the $E - X$ systems, indicating that more highly excited orbitals than (2) or (3) are here involved.

This comparatively simple situation, which obtains for the lighter molecules of the group, is in strong contrast with that for the heavier molecules, particularly for SnSe, SnTe and the lead compounds. In PbO, for example, the absorption region of longer wave-length ($\lambda > 2500$ Å.) shows at least six band systems[7]. The characters of the upper states of these systems have now been determined by rotational analysis of several bands of each system from plates taken on a 6·5-m. grating spectrograph. A summary of the results is given in Table 1. The results for the $A - X$ system agree with those from the less-extensive analysis of Christy and Bloomenthal[8]; however, their analysis of the $D - X$ system, which indicated that state D was ${}^1\Sigma^+(0^+)$ is incorrect.

In interpreting these results, two possibilities arise: either (i) new low-lying electron configurations other than (2) and (3) become of importance in the heavier molecules, or (ii) the coupling shifts to Hund's case-*c*. The latter is perhaps the more attractive suggestion. The case-*c* states of (2) and (3) are as follows :

$$\pi^4\sigma\pi^* \rightarrow 2,1,1,0^+,0^- \qquad (2)$$

$$\pi^3\sigma^2\pi^* \rightarrow 3,2,2,1,1,1,0^+,0^+,\ 0^-,0^- \qquad (3)$$

Table 1. Summary of Constants for ^{208}PbO

State		T_0	ω_e	$x_e\omega_e$	B_e	$10^3\ \alpha_e$	r_e Å.	Notes
E	0^+	34680	[440]	—	[0·2382]	[1·4]	2·18$_3$	1
D	1	30464	530·5	2·92	0·2711	3·1	2·046	2
C′	1	25720	[475]	—	0·248	1·8	2·14	2, 3
C	0^+	24108	[534]	[3·9]	0·254	2	2·11	4
B	1	22531	493·4$_7$	2·26	0·2646$_3$	2·6	2·070$_9$	2
a	?2							2
A	0^+	20088	451·7	3·33	0·2586$_9$	1·3$_8$	2·095$_3$	
X	0^+	0	721·8	3·70	0·3073$_7$	2·1$_2$	1·921$_6$	

(1) There are strong perturbations in state *E*, so that the constants for this state are uncertain. The values of v' for this system have been increased by 1, following a study of the isotope effect.

(2) Perturbations in *R*, *P* and *Q* branches at about the same value of J' are observed in some of the levels of *B*, *C′* and *D*. The form of these suggests that they are caused by one or more $\Omega = 2$ states.

(3) The system $C' - X$ was observed by Howell (ref. 9) as a single $v'' = 0$ progression.

(4) The values of v' for the $C - X$ system have been increased by 2, following a study of the isotope effect.

If these are all bound states, there are predicted three absorption systems $0^+ \leftarrow X$ and five systems $1 \leftarrow X$. The 0^- and 2 states would be identifiable in the absorption spectrum only through interactions with the $\Omega = 1$ states. The number and the character of the excited states so far observed suggest that their interpretation as case-*c* states may be the correct one. It is hoped that work, now in progress, of the numerous perturbations in these systems will help to elucidate this problem.

Kirkendall Effect in Gases

An experiment has been described[1] in which the motion of fine particles of ammonium chloride smoke in a diffusing gas mixture was considered evidence for a Kirkendall effect in gases. Only a rough semi-quantitative interpretation could be given at the time in terms of the usual phenomenological theory of the Kirkendall effect. Subsequent theoretical and experimental work[2,3] on gaseous diffusion has shown that the phenomenological theory cannot be correct for gases, but that the classical kinetic theory of gases is capable of accounting for the phenomenon quantitatively. We wish to point out that it is now possible to give a quantitative interpretation to the previous measurements.

The experimental results may be summarized in terms of the usual intrinsic diffusion coefficients. The observed motion of the finest particles of the smoke corresponded to a difference of intrinsic diffusion coefficients of $(D_2 - D_1) \simeq 0{\cdot}63$ cm.²/sec. for $1 = \mathrm{CF_2Cl_2}$ and $2 = \mathrm{H_2}$ at 20° C. and 1 atm., in the absence of gravity. This value is probably an upper limit, since the necessary correction for the rate of sedimentation of the smoke particles under gravity appeared to be somewhat too large as it was made.

If the smoke particles are much larger in diameter than the mean free path of the gas molecules, they should drift with the bulk velocity (that is, the mass average velocity) of the diffusing gas mixture and thus act as true Kirkendall markers. In this case the difference of the intrinsic diffusion coefficients is given by equation (23) of reference 2, and can be written as:

$$D_2 - D_1 = \frac{m_1 - m_2}{x_1 m_1 + x_2 m_2} D_{12} \qquad (1)$$

where the m's are the molecular masses, the x's are mole fractions, and D_{12} is the interdiffusion coefficient, which has been found[3] to have a value of 0·38 cm.²/sec. Taking $x_1 = x_2 = 1/2$ (at the diffusion boundary), we calculate from (1) that $(D_2 - D_1) = 0{\cdot}73$ cm.²/sec. This is larger than the experimentally observed upper limit of 0·63 cm.²/sec., so the smoke particles cannot be regarded as true Kirkendall markers.

If, however, the smoke particles are smaller in diameter than the mean free path, their behaviour is different, and the theory for such a case has been given by Waldmann[4]. According to his equation (7.20), the particles move with a velocity corresponding to:

$$D_2 - D_1 = \frac{m_1^{1/2} - m_2^{1/2}}{x_1 m_1^{1/2} + x_2 m_2^{1/2}} D_{12} \qquad (2)$$

from which we calculate $(D_2 - D_1) = 0{\cdot}59$ cm.²/sec. This is in good agreement with the observed upper limit. In equation (2) we have assumed that Waldmann's coefficients of diffuse scattering of the gas molecules from the smoke particles were equal to unity, which is in accord with experiment[5]. It is apparent that the finest smoke particles are probably smaller than the mean free path. This is physically reasonable, since the relevant mean free path in the experiments was of the order of 0·1μ.

Although the smoke particles were thus not true Kirkendall markers, they could have been used as such, since their velocity was proportional to the bulk velocity, although not equal to it. From equations (1) and (2) the relation is:

$$v = \left[\frac{m_1 - m_2}{m_1^{1/2} - m_2^{1/2}}\right]\left[\frac{x_1 m_1^{1/2} + x_2 m_2^{1/2}}{x_1 m_1 + x_2 m_2}\right] v(\text{smoke}) \qquad (3)$$

or:

$$v = [1 + 2(m_1 m_2)^{1/2}/(m_1 + m_2)]\, v(\text{smoke}), \quad \text{if } x_1 = x_2 \qquad (4)$$

where v is the mass average (bulk) velocity and v(smoke) is the velocity of the smoke particles.

ENGINEERING

Effective Contact Stresses and Friction

The earliest statement concerning statical frictional forces between rigid bodies is usually attributed to Coulomb (about 1776). The principle of Coulombic friction is that the force (F) required to generate translation of one body relative to another is directly proportional to the external force (W) transmitted across the contact plane, so that:

$$F = \mu W \qquad (1)$$

where μ is the coefficient of (static) friction.

In 1950, Bowden and Tabor[1] published their, now well-established, concept of asperity contact giving rise to plastic junction. According to Bowden and Tabor the frictional force (F) is a product of the total area of the junctions (Aj) and their shear strength (Sj), hence:

$$F = AjSj \qquad (2)$$

and it was further postulated that the area (A) is given by the normal force (W) divided by the flow pressure (p) so that:

$$W = pAj \qquad (3)$$

and thus :

$$\mu = \frac{F}{W} = \frac{Sj}{p} \qquad (4)$$

and it has been found that for most metals the coefficient μ is independent of the normal load.

The purpose of this communication is to direct further attention to equation (3).

Terzaghi[2] was the first to state the law of effective stress in relation to inter-particle contact in a two-phase medium. Terzaghi's effective stress law states that the effective stress (σ^1) is given by:

$$\sigma^1 = (\sigma - u) \qquad (5)$$

where σ is the applied (external) normal stress and u is the positive hydrostatic pressure in the fluid surrounding the 'solid' particles.

This law entails two basic assumptions: (i) that a continuous surface exists which passes through the contacts between particles; (ii) that the area of contacts (plastic junctions) is insignificant compared with the total area of the continuous surface. Experimental work in the field of soil mechanics has established the validity of this law within practical limits[3].

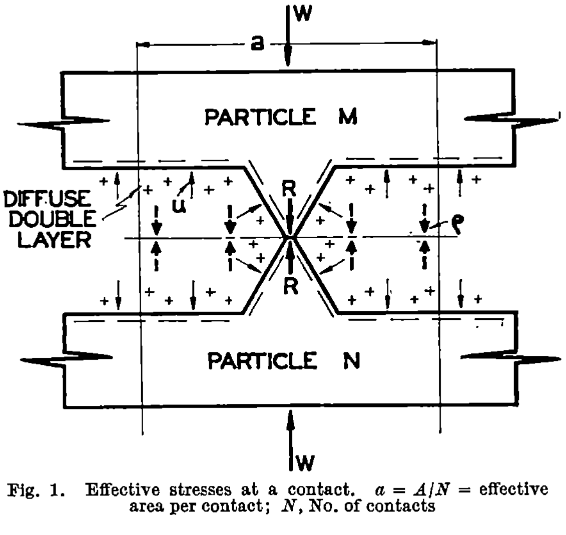

Fig. 1. Effective stresses at a contact. $a = A/N$ = effective area per contact; N, No. of contacts

Following a study of clay structure during recent years[4] I have extended equation (5) to take account of surface activity between proximate particles, and the effective stress equation now takes the form:

$$\sigma^1 = (\sigma - u + \rho) \qquad (6)$$

where ρ is the effective stress component derived from surface forces.

Consider the simplified system shown in Fig. 1.

The force R transmitted across the junction is made up of three parts.

$$R = W - \mu.a. + \rho.a. \qquad (7)$$

assuming that ρ, the resultant of all surface physico-chemical effects (for example, Van der Waals forces, double-layer repulsions, primary or secondary valence bonds at the junction), is attractive in character.

Then according to the Bowden–Tabor concept the frictional force (Fj) required to shear the junction is:

$$Fj = \mu R$$

thus:

$$Fj = \left(\frac{W}{N} - u.a. + \rho.a.\right) \qquad (8)$$

$$= \frac{W}{N} - \frac{uA}{N} + \rho\frac{A}{N}$$

The total frictional or shear force (F) is then given by:

$$F = \sum_{j=1}^{N} Fj = \sum_{j=1}^{N} \mu R = N\mu R$$

It follows that the shear stress (S) is:

$$S = \frac{F}{A} = \frac{N}{A}\mu R$$

$$= \frac{N}{A}\mu\left(\frac{W}{N} - \frac{uA}{N} + \rho\frac{A}{N}\right)$$

$$= \mu(\sigma - u = \rho) \qquad (9)$$

that is, the shear stress, on the basis of the assumptions given, is independent of the number of asperities.

Equation (9) is the effective stress expression governing friction in pure systems, that is, those where the junctions are all physically and chemically alike.

For composite materials, such as soils, the μ term is conventionally replaced by the term $\tan \varphi_e$ (Hvorslev, 1957), where φ_e is called the angle of internal friction or alternatively $\tan \varphi_e$ is the coefficient of macro-fraction and is a statistical mean of the component micro-friction effects[5].

Although equation (9) was derived with clay–water–electrolyte systems principally in mind it is thought to be of more general application. For example, if both u and ρ are effectively zero we have the condition of Coulombic friction applicable to dry granular materials; at the other end of the scale we may have conditions where both σ and u are insignificant compared with ρ, as with the internal structure of metals and certain adhesives. This latter concept may even be extrapolated to the inter-atomic level in the solid state.

Yet another possible application concerns lubrication. If, for the present, viscosity effects are neglected, then for invert surfaces ($\rho = 0$) the condition of 'dry' friction is obtained when $\mu = 0$, even though fluid may be present and the necessary condition for hydrodynamic friction is that $\sigma = u$. Between these two extremes there is a range of u values, the actual value of u and therefore that of the apparent coefficient of friction being dependent on the ambient conditions.

This latter approach is at present being considered in a study of high-speed skidding characteristics in relation to airfield pavements.

CHEMISTRY

Quantitative Estimation of Peak Areas in Gas-Liquid Chromatography

QUANTITATIVE estimation of peak areas on gas-liquid chromatograms has been carried out by a variety of methods, which include triangulation, cutting out the peak areas and weighing the cut paper, planimeter tracing and use of an integrator built into the recorder. A new method recently proposed by Bartlet and Smith[1] is based on evidence that the peaks obtained with a well-designed chromatograph closely approximate a normal or Gaussian distribution curve.

The equation for this type of curve is given as :

$$Y = \frac{A}{\sigma\sqrt{2\pi}}\, e^{-\frac{1}{2}(X/\sigma)^2} \qquad (1)$$

where Y is the height of the curve measured at a distance x from the mean, A is the area and σ is the standard deviation. At the mean or central peak of the curve $x = 0$, $Y = h$ or peak height and equation (1) becomes :

$$h = \frac{A}{\sigma\sqrt{2\pi}} \qquad (2)$$

$$\text{or } A = 2{\cdot}507\, h\sigma \qquad (3)$$

The peak height h may be measured directly from the chromatogram and the standard deviation σ may be obtained from the peak width w at various heights since $w = \sigma$ at $0{\cdot}882h$, $w = 2\sigma$ at $0{\cdot}607h$, $w = 3\sigma$ at $0{\cdot}324h$ and $w = 4\sigma$ at $0{\cdot}134h$. The area under the curve may therefore be calculated from equation (3).

Bartlet and Smith also showed that σ is a linear function of the retention time t_R, and this has been confirmed in our studies with fatty acid esters. It is thus evident that the product of peak height and retention time may also be used as a measure of peak area. This is much better than using the product of peak height and standard deviation, since retention times are normally measured in any event and can be obtained with greater ease and precision than the standard deviations of the peaks.

The product of peak height and retention time was suggested by Pecsok as a measure of peak area[2], but no theoretical or experimental proof of its validity was provided and it does not seem to have been used very widely. The method was therefore compared in our Laboratory with the paper weighing and triangulation methods, using chromatograms of mixtures of fatty acid esters. Examples are shown in Table 1. Although the results obtained with the new method are not in perfect agreement with those of the other methods, they are nevertheless adequate for most biological studies, and the convenience of using the new method makes it very useful for routine analytical work.

In applying this method to peaks which are only partially resolved, it should be noted that the measured peak heights will be higher than the true peak heights by amounts which are determined by the degree of overlap and by the relative amounts of the components. A correction for this may be obtained by application of equation (1) as shown by Bartlet and Smith. Alternatively, if pure samples of the overlapping components are available, they may be chromatographed individually and correction factors obtained by direct measurement. In practice, the correction factors are very small, even for peaks with serious overlap, and although successive corrections are theoretically required, they are rarely, if ever, needed.

The present method of determining peak areas has an advantage over the paper-weighing method in that it allows the chromatogram to be saved for future reference. It is less laborious than triangulation and gives more reproducible results since it avoids the subjective variation involved in the drawing of triangles. It may also be noted that the units of measurement are unimportant as long as the same

	(18 : 2)	18·0	16·6	328	16·7	24·5	12·6	17·0

Fatty acid esters were separated on a 6 ft. column packed with butanediol succinate (Craig ester) on Chromosorb *W* (1 : 4). A Barber–Colman chromatograph with a radium source for the ionization detector was employed. The column was operated at 200° and the flash heater and cell bath at 255°. Argon at 20 lb./in.² flowed at the rate of 150 ml./min.

* Minor peaks were not included in these calculations.

units are used for each component of the mixture. Thus, in the examples given, peak heights were measured in mm. and retention times in minutes. The convenience of this method and the probability that further improvements in instrumentation will give curves more closely approaching the Gaussian distribution curve suggest it as a method of choice for future quantitative work in gas-liquid chromatography.

Compressibility and Specific Evaporation Resistance of the Monolayers of Long-Chain Alcohols and Glycol Monoalkyl Ethers

THE monolayers of long-chain compounds such as cetyl and stearyl alcohols are being used extensively to minimize the loss of water by evaporation in reservoirs[1]. Permeability of water vapour through a monolayer depends on, among others, the magnitude of the van der Waals type of cohesive forces of the film molecule with its neighbours, and on the adhesive force between the monolayer and the water sub-phase. Further extension of the *n*-alkyl chain and/or suitable modification of the terminal polar group would, therefore, make a monolayer more effective in reducing evaporation.

In view of various such considerations as structural, stereochemical and spreading property, and economic availability, we have been restricted to the C_{16}–C_{22} *n*-alkyl compounds and prompted to modify and thus increase the interaction of the polar end-group with the water sub-phase. Accordingly, we synthesized a series of glycol monoalkyl ethers, R–OCH_2CH_2OH (R being an *n*-alkyl chain containing 16–22 carbon atoms), and reported[2] their superior water evaporation resistance behaviour compared to the alcohols. This communication describes the preliminary results on the compressibilities and the specific evaporation resistances of the monolayers of these as well as those of the alcohols for comparison.

The preparation and purification procedures of the compounds used were indicated earlier[2]. The melting and softening point, micro-analysis, infra-red analysis and, in addition, equilibrium surface pressure[3] of the film spread from solid particles were used as criteria of purity. Monolayers were formed from solutions in A.R. distilled (60–80° C.) petroleum ether on a clean surface of double-distilled water in an all-glass Langmuir trough. The film was compressed by means of a paraffin barrier and the pressure was measured with a horizontal film balance.

From a study of the pressure/area isotherms, it has been observed that, initially, after a region of very low pressure (~ 1 dyne/cm.) the film is transformed into a so-called liquid condensed state. On further compression, the pressure rises steeply due to the formation of a highly non-compressible, compact film in the solid state. The transition pressures for liquid condensed to solid state vary from 10–25 dynes/cm. in the case of alcohols and 25–35 dynes/cm. in the case of glycol ethers when the chain length is increased from C_{16} to C_{22}. The calculated compressibility data $k = -\left(\frac{1}{A}\ \frac{dA}{d\pi}\right)$ are given in Table 1.

Table 1. COMPRESSIBILITY (25° C.)

n-Alcohol	Liquid condensed state $k \times 10^3$	Solid state $k \times 10^4$	Glycolmono-alkyl ether	Liquid condensed state $k \times 10^3$	Solid state $k \times 10^4$
C_{16}	5·43	13·22	C_{16}	7·86	12·82
C_{18}	5·03	6·80	C_{18}	7·29	7·82
C_{20}	4·59	7·09	C_{20}	—	—
C_{22}	1·93	6·97	C_{22}	5·02	6·98

The results for the C_{16} and C_{18} *n*-alcohols are in agreement with the reported data[4]. It is noticed that the liquid condensed state is more compressible than the solid state. However, the films formed by the glycol ethers are significantly more compressible than those of the alcohols in the liquid-condensed state, which may be attributed to differences in the dipole-repulsion property and the geometry of the polar end-groups in the two series.

Following the method developed by Langmuir *et al.*[5] the specific resistance (ν) of the film was evaluated from the expression:

$$\nu = \left[A(w-w_0)\ \frac{t}{M}\right]_{\text{film}} - \left[A(w-w_0)\ \frac{t}{M}\right]_{\text{no film}}$$

where A is the area of the desiccant (lithium chloride) exposed; w and w_0, the concentrations of water vapour in equilibrium with water and desiccant respectively; M, the mass of water absorbed by the desiccant in time t sec. The temperature of the desiccant as well as of the water surface were measured by using thermistor probes through a d.c. bridge circuit. All the precautions prescribed by La Mer *et al.*[6] were taken. The results obtained at 25° C. at different surface pressures are given in Fig. 1.

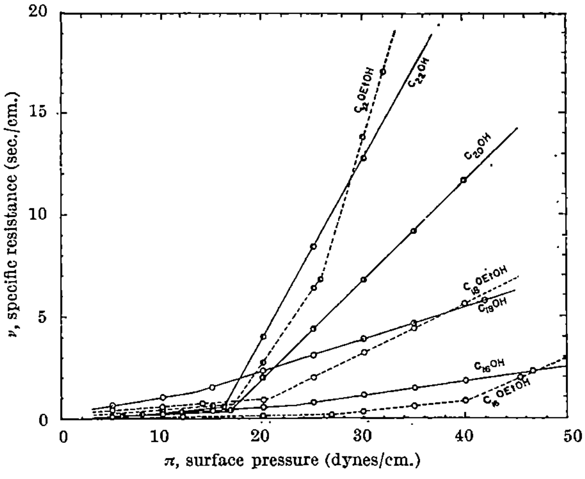

Fig. 1

The results for C_{16} and C_{18} *n*-alcohols are in agreement with reported data[6,7]. It is seen that, at lower pressures up to 16–18 dynes/cm., the resistance in all cases is very low (~1 sec./cm.). However, ν increases rapidly at higher pressures and also with the increase in the length of the chain. In the expanded condition of the film in the low-pressure region, the interaction between film molecules is very weak, requiring little energy to create a hole for the water molecule to escape. However, strong interaction between them is indicated by the sharp rise of pressure with further decrease in area when the formation of continuous, close-packed film starts through vertical orientation of, and strong intermolecular cohesive binding between, the long chains. The observed increase of ν with the length of the chain in both the series is due to an increase in the cohesive binding between the film molecules, and hence the increase in the activation energy required to create a hole in the film.

It is interesting to note that, between the two series, the ν-values in general are lower for the glycol ethers (shown as *R*–OEtOH in Fig. 1) than for the corresponding alcohols at the same pressure, and this is in accordance with the fact that compressible films are less effective. After about 30–40 dynes/cm. pressure, however, the C_{22}- and C_{18}-glycol ethers exhibit higher ν-values than the alcohols and this fact supports our observations reported earlier[2], that the glycol ethers are better retarders of evaporation than the alcohols at high (equilibrium) film pressure conditions.

That the superior performance of the glycol ethers compared with the corresponding alcohols may be ascribed to higher rate of spreading (surface solution of the ethers being greatly facilitated due to the greater interaction of the polar end with the water sub-phase), higher equilibrium film pressure in the significant temperature-range, and greater adhesive interaction with the water sub-phase, will be dealt with in a separate communication.

Electronic Properties of Imidazole

The existence of semiconduction has been demonstrated in a variety of different classes of organic compounds such as condensed aromatic hydrocarbons, charge-transfer complexes, pyrolized polymers, and stable free radicals. With few exceptions, the electrical conductivities are small, and the energies of activation for the conduction process are high. But the fact that even small conductivities are displayed suggests that some kind of intermolecular interaction takes place which, in an electric field, gives rise to electronic conduction. It is suggested that this interaction is molecular orbital overlap. The extent of orbital overlap is a function of molecular structure and hence, if semiconduction arises from such overlap, it is not surprising that semiconduction activation energies correlate with properties which are also a function of molecular structure, such as the molecular ionization energy, electron affinity, and excitation energy of the ground-triplet state transition[1,2]. One of the entities which influences these properties is the number of (the more easily polarizable) π-electrons. As the number of these increases in a conjugated system, there is a trend toward smaller activation energies of conduction, indicating that the probability of achieving overlap is enhanced by the presence of a large number of π-electrons. However, if the overlapping of molecular orbitals gives rise to semiconduction, then any other factors which contribute to such overlapping should also encourage semiconduction, even if only few π-electrons are present in the individual molecule. Since intermolecular hydrogen bonds may provide such overlap, it might be expected that activation energies in hydrogen-bonded compounds should be lower than anticipated solely on the basis of the number of π-electrons.

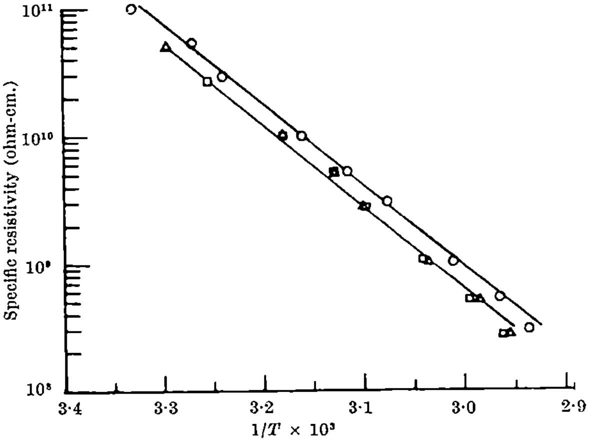

Fig. 1. Specific resistivity of imidazole. ○, run 2, 720 V./cm.; △, run 3, 72 V./cm.; □, run 4, 72 V./cm.

Supporting evidence for this view has now been found in a study of the resistivity of imidazole. Imidazole is extensively hydrogen-bonded as adduced from its relatively high melting and boiling points and from its spectra. In the present work, imidazole was purified by several recrystallizations, distillation at reduced pressure, and zone-refining. The resistivity was measured as a function of temperature on a compacted polycrystalline sample with the results shown in Fig. 1. The energy gap computed from the equation $\rho = \rho_0 \exp(E/2kT)$ was 2·6 eV. in the temperature range of 28–66°. Slightly higher resistivities were obtained at a higher potential stress; it is not known whether this is a significant effect. Energy gaps ranging between 2·8 and 3·0 eV. were obtained on several other samples which had not been as rigorously purified.

Energy gaps of compounds which contain only four π-electrons are not available for comparison with that of imidazole (which also contains four π-electrons). The energy gap of benzene (which contains six π-electrons) has not been experimentally determined but has been estimated[3] as approaching 5 eV. If the number of conjugated π-electrons were the sole factor which determines the energy gap, one might have expected that of imidazole to be much greater than the experimentally found value of 2·6 eV. It is concluded that the orbital overlap provided by hydrogen-bonding effectively facilitates semiconduction.

We thank Messrs. E. J. McGowan and J. Howard for valuable technical assistance. This research was supported by the Air Research and Development Command, United States Air Force.

Formation of Boron Nitride in Diborane-Hydrazine Flames

Although reactions of metals with nitrogen or nitrogen compounds leading to nitrides are well known[1], the literature on combustion is devoid of descriptions of flames from the reaction between boron hydrides and nitrogen hydrides (ammonia, hydrazine). This communication reports a steady-state flame of diborane and hydrazine, in which the reaction products consist principally of boron nitride and hydrogen, according to the reaction $B_2H_6 + N_2H_4 \rightarrow 2BN + 5H_2$.

Even though the value of the heat of formation of boron nitride is not fully established (27–32 kcal./mol. in ref. 2, 60·2 kcal./mol. in ref. 3) the above reaction is sufficiently exothermic for it to proceed without difficulty. Examination of this system is complicated, however, by a rapid gas-phase reaction of boron hydrides with ammonia, hydrazine or amines, leading to a variety of solid 'adducts'[4], which prevents premixing of the components prior to combustion. To overcome this problem a novel burner was constructed, consisting of a closely spaced array of capillaries (Fig. 1) by means of which a 'multi-diffusion' flame is established in a laminar mixing zone. This type of burner is of general utility for combustion studies in which premixing of components is impractical or impossible, but where it is desirable to investigate the reaction products from flames approaching the premixed state.

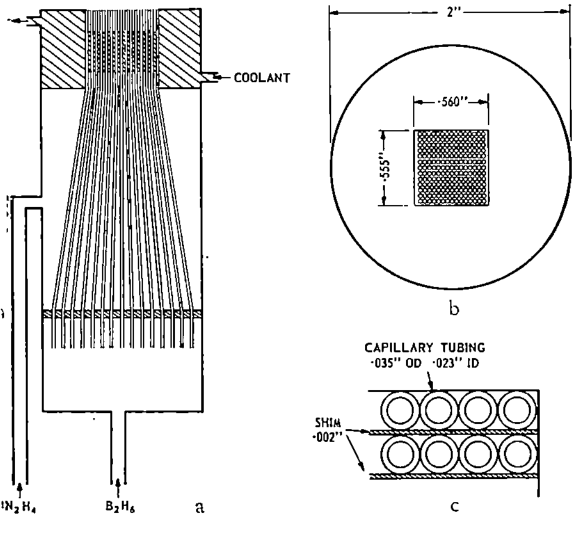

Fig. 1. Schematic diagram of capillary multidiffusion burner. *a*, Cross-section, showing arrangement of separate feeds for two incompatible gaseous components; *b*, top view; *c*, details of capillary assembly. Symmetrical assembly of tubes is essential to provide uniform gas flow at top of the burner. Metal shims are used as spacers between rows of capillaries

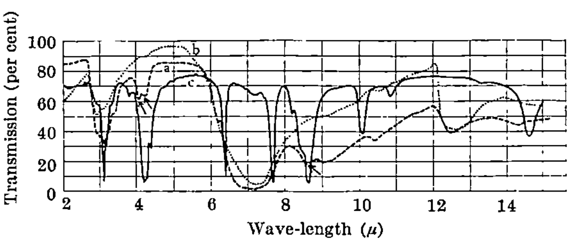

Fig. 2. Infra-red spectra of: *a*, solid reaction products from the B_2H_6—N_2H_4 flame; *b*, boron nitride; *c*, diborane-hydrazine adduct (Callery Chemical Co.). The arrowed absorption bands in *a* are due to the presence of small amounts of adduct

To achieve the boron nitride reaction a flat hydrazine decomposition flame is established first (requiring thermostatting the burner and fuel-feed above 100° C. to obtain an adequately high hydrazine vapour pressure). Subsequent addition of diborane through the separate feed system leads to a flame with copious evolution of solid reaction products consisting predominantly of boron nitride. As shown by infra-red (Fig. 2) and chemical analyses only small amounts of bound hydrogen appear as impurity in the solid.

By measurement of the flame temperature and the composition of the products of combustion an independent value for the heat of formation of boron nitride is being obtained.

This work was carried out under contract *NOrd* 7386 of the U.S. Navy.

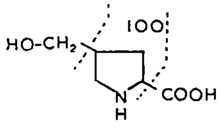
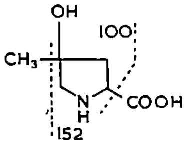
Determination by Mass Spectrometry of the Structure of Proline Derivatives from Apples

Hulme[1] and Urbach[2] independently isolated a new amino-acid from apples, and the isomeric structures I[2] and II[1,3] were proposed for these substances on the basis of elemental analysis, colour reactions and chromatographic properties[1–3]. The infra-red spectra of these compounds proved to be superimposable, and this indicated that the compounds were identical, but it did not permit a decision between the alternative structures[3].



I



II

Ia

III

It seemed that this problem could now be resolved by mass spectrometry, a method recently introduced into amino-acid chemistry[4,5]. Therefore, small samples of the original isolates were procured from Dr. A. C. Hulme and Mrs. G. Urbach, respectively. For these samples we are grateful.

The ethyl esters of the two compounds were prepared by treatment of 1 mgm. of each substance with boiling ethanolic hydrochloric acid and by conversion of the product into the free ester[6]. The mass spectra of the ethyl ester of the two compounds (Fig. 1) were identical in every respect: this corroborated the presumed identity[3] of the two amino-acids which had been isolated independently.

The mass spectra exhibit a very intense peak at *m/e* 100 due to loss of the carbethoxy group (73 mass units) from the molecule, the molecular weight of which is 173. This evidence relates to the structure I, and this conclusion is also supported by a peak at mass 174, which exhibits the characteristics of an $M + 1$ peak[4]. An appreciable peak is also found at mass 31 (CH_2OH) and at mass 142 ($M - 31$), which can be reconciled only with the structure I. By contrast, one would expect from structure II a considerable peak at mass 158 ($M - 15$), but none at 31 and 142, because the loss of the methyl group would lead to a carbonium ion which would, in turn, be well stabilized by the high degree of substitution as well as the oxygen atom.

Furthermore, it is now possible to deduce the stereochemistry of this amino-acid, because the mass spectrum of the ester remains substantially unchanged after the sample is kept for 30 min. in the hot (140° C.) inlet system of the mass spectrometer. A substance with the *cis*-configuration of the carbethoxy- and hydroxy-methyl groups should, under these conditions, undergo lactone formation at least in part: because this does not occur, the *trans*-structure I*a* is assigned to this compound. By the same argument, the otherwise possible structure III is eliminated, because such a substance in the form of its ester should lactonize readily under the conditions specified, whether the configuration is *cis* or *trans*.

The assignment of the optical configuration is, of course, not possible from these experiments, and this must await the final correlation of this amino-acid with proline (presumably L-proline).

After the work described, one of us (F. C. S.) learned through correspondence (letter of January 5, 1961) that Dr. G. W. Kenner and Dr. L. F. Burroughs had examined a sample identified with that of Hulme[1] and concluded that "this turns out to be a hydroxymethyl compound rather than a methylhydroxy derivative of proline, and we hope to correlate it with methyl proline". Therefore, the identity of these compounds as the *trans* form of 4-(hydroxymethyl)-proline is now established.

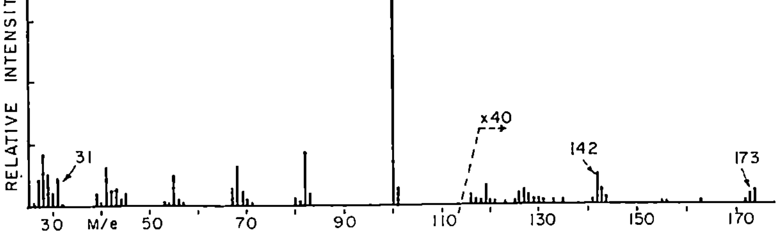


Fig. 1. Mass spectrum of the ethyl ester of the proline derivative isolated by Hulme from apples. Peaks above mass 115 are enlarged 40-fold. All peaks of ⩾ 1 per cent of the intensity at *m/e* 100 are shown below mass 116 and of ⩾ 0·05 per cent above mass 116. The spectrum of the compound isolated by Urbach was indistinguishable from that shown

Determination of Lead in Urine by Atomic Absorption Spectroscopy

MOST methods for the determination of traces (0·01–1 p.p.m.) of lead in urine require prior removal of organic matter and concentration of the lead by ashing. These methods have several drawbacks: the time required for ashing; possible interference from other metals such as bismuth; and the need for careful purification of a variety of reagents to keep the blank reading at a reasonably low level.

Several methods have been described in which the lead is co-precipitated with calcium oxalate and estimated colorimetrically[1] or polarographically[2]. However, it is doubtful whether much time is saved thereby, and there is evidence[3] that under these conditions lead is not completely precipitated from urine, especially where the patient has been treated with complexing agents such as ethylenediaminetetraacetic acid or 2,3-dimercaptopropanol.

Allan[4] has recently shown that trace quantities of copper in soils and plant ash can be determined by extraction with a chelating agent into an organic solvent and spraying this solution directly into the burner of an atomic absorption spectrophotometer.

I have found that lead can be quantitatively extracted from urine by ammonium pyrrolidine dithiocarbamate[5] and methyl *n*-amyl ketone at a *p*H sufficiently low (1·5–4·5) to avoid precipitation of the phosphates. The lead may thus be concentrated by a factor of 100 or more and determined by spraying the ketone solution into the 10-cm. air-coal gas flame of the atomic absorption spectrophotometer described by Box and Walsh[6]. The absorption of the lead line at 2833 Å. is measured and the instrument is calibrated by extracting and measuring a similar quantity of urine to which a known amount of lead has been added.

Since we are concerned only with the concentration of lead in the ketone phase the partial emulsification which invariably occurs does not affect the accuracy of the determination. After shaking with ammonium pyrrolidine dithiocarbamate and methyl *n*-amyl ketone the urine is allowed to stand for 5 min., and most of the lower layer is discarded, the last 5 ml. or so being transferred, together with the upper layer and the emulsion at the interface, to a centrifuge tube. After centrifuging for 5 min. a partial separation of the layers occurs; the upper layer is removed with a fine Pasteur pipette and the remainder of the liquid stirred thoroughly and centrifuged again. The upper layer is pipetted off once more, and the combined quantities are sufficient for a measurement.

Table 1 shows the recovery of added lead from normal urine, while Table 2 compares the results obtained for pathological specimens by the dithizone method and the atomic absorption technique. It will be seen that the results of the new method are in satisfactory agreement with those of the classical one.

Table 1. RECOVERY OF LEAD ADDED TO NORMAL URINE (P.P.M.)

Added	Recovered
0·10	0·10
0·20	0·21
0·30	0·27
0·40	0·41
0·50	0·56

50 ml. of urine (pH 4) containing the added lead was extracted with 0·5 ml. of 4 per cent ammonium pyrrolidine dithiocarbamate and 1·5 ml. methyl *n*-amyl ketone. Similar specimens to which 15 μgm. of lead had been added were extracted in the same way to serve as standards.

Table 2. COMPARISON OF COLORIMETRIC AND ATOMIC ABSORPTION METHODS FOR DETERMINATION OF LEAD IN URINE

Specimen No.	Lead content (p.p.m.) Colorimetric	Lead content (p.p.m.) Atomic absorption
1	0·03	0·04
2	0·04	0·07
3	0·06	0·07
4	0·07	0·07
5	0·18	0·14
6	0·26	0·28
7*	0·76	0·72

* From a patient undergoing treatment with ethylenediamine-tetraacetic acid.

The atomic absorption method is particularly well suited for the measurement of very low lead concentrations (<0·1 p.p.m.) as it is specific for lead and yields a negligible blank value. By using larger volumes of urine (100–200 ml.) it is possible to measure a lead concentration of 0·02 p.p.m. with a standard deviation of 0·002 p.p.m.

The method is also applicable to other heavy metals and indeed zinc and cadmium, for which the detection limit in aqueous solution is about 0·03 p.p.m.[7], can be determined by direct measurement on the urine itself without prior extraction.

I am indebted to Dr. Alan Bell and Mr. Graham Blanks for supplying the pathological specimens and for measuring their lead contents colorimetrically.

BIOCHEMISTRY

Electrophoretic and Immuno-electrophoretic Patterns of Extracellular Diphtheria Proteins from Culture Filtrates of Different Iron Concentrations

IN cultures of *Corynebacterium diphtheriae* the toxin is produced only within a relatively narrow range of iron concentration. Excess of iron inhibits toxin formation, but the mechanism of this phenomenon is not explained. Toxigenicity is strictly associated with the presence of prophage in diphtheria bacillus cells, and it has been recently suggested that iron probably affects toxin production by causing induction of the prophage–host system[1]. At iron excess a certain amount of atoxic, extracellular protein is found in the culture filtrate, but their physico-chemical and immunological properties are little known. A closer characterization of these components, which will be hereafter referred to as 'Fe-proteins', appears useful for work on toxin formation.

Paper electrophoresis has shown extracellular diphtheria proteins to constitute a complex system, comprising at least six fractions, for which the following nomenclature has been proposed[2]: fraction *D*, amounting to about 65–80 per cent, more rapid fractions ρ_1 and ρ_2, and three fractions slower than *D*, namely: σ_1, σ_2, and σ_3 (Fig. 1). Diphtheria toxin, that is, the factor endowed with lethal and dermonecrotic properties, is localized in the cathodic part of fraction *D*.

The electrophoretic pattern of 'Fe-proteins' has shown striking difference as compared with the pattern of extracellular proteins obtained at iron concentration optimal for toxin production (Fig. 2). It is characterized by a strongly diminished content

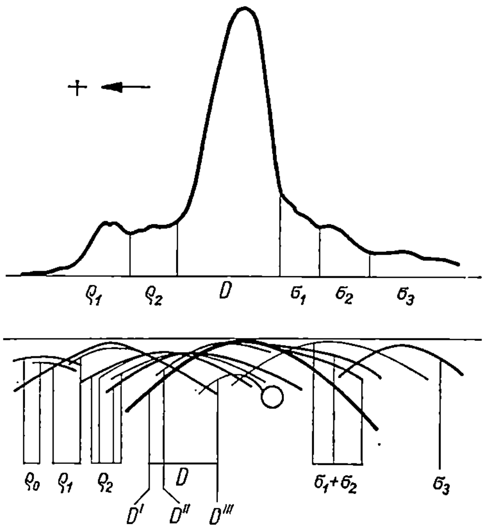

Fig. 1. Electrophoretic and immuno-electrophoretic patterns of extracellular diphtheria proteins obtained at iron concentration optimal for toxin production. Preparation of extracellular proteins obtained by precipitation with ammonium sulphate at 0·66 saturation from a 5-day culture of *C. diphtheriae PW*8. Iron concentration in the culture medium (acid hydrolysed casein), 0·12 μgm. iron/ml. Flocculation titre of the crude culture filtrate, 110 Lf./ml., flocculation activity of the preparation, 2080 Lf./mgm. protein nitrogen, dermonecrotic activity. 2×10^8–$2{\cdot}5 \times 10^8$ minimum reacting dose/mgm. protein nitrogen. Paper electrophoresis; Michaelis buffer pH 9·0; ionic strength, $\mu = 0{\cdot}1$. Densitometric curve after amido-black staining (ref. 2). Immunoelectrophoresis: Michaelis buffer, pH 9·0; ionic strength, $\mu = 0{\cdot}05$ (ref. 3)

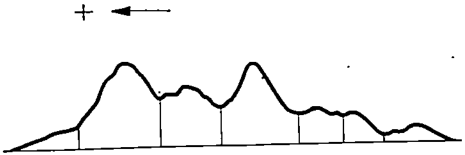

Fig. 2. Electrophoretic pattern of 'Fe-proteins'. Preparation of 'Fe-proteins' obtained by precipitation with ammonium sulphate at 0·66 saturation from a 5-day culture of *C. diphtheriae PW*8. Iron concentration in the culture medium, 1·0 μgm iron/ml. Flocculation titre of the crude culture filtrate less than 2·5 Lf./ml., dermonecrotic activity, 2·5 × 10^6 minimum reacting dose/mgm. protein nitrogen. Paper electrophoresis: Michaelis buffer, *p*H 9·0; ionic strength, $\mu = 0·1$. Densitometric curve after amido-black staining

of fraction *D*. In experiments involving determination of relative electrophoretic mobilities, it has been found that fraction *D* of the 'Fe-proteins' migrates with a mobility corresponding to the material of the anodic part of fraction *D* of extracellular proteins obtained at iron concentration optimal for toxin production. Running electrophoresis simultaneously on the same strip proved all the other fractions of the 'Fe-proteins' to be identical, with respect to their mobility, with corresponding fractions of extracellular diphtheria proteins obtained at iron concentration optimal for toxin production. In immunoelectrophoretic experiments the immunological identity of precipitating components of those fractions has been demonstrated.

The immuno-electrophoretic pattern of 'Fe-proteins' does not contain the *D'* line, which is the principal component of the pattern of extracellular diphtheria proteins obtained at optimal iron concentration[3]. When, however, immuno-electrophoretic patterns of extracellular proteins obtained at iron concentration optimal for toxin production were developed with anti-toxic sera absorbed with 'Fe-proteins' they were found to contain two additional precipitation lines besides line *D'* : line *D'''* and one localized within fraction ρ_2 (Fig. 3). These experiments have clearly demonstrated that excess iron inhibits the production of at least three precipitating components.

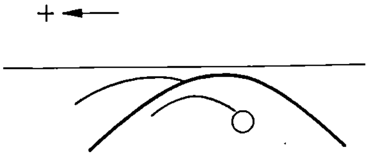

Fig. 3. Immuno-electrophoretic pattern of extracellular diphtheria proteins obtained at iron concentration optimal for toxin production. Flocculation activity of the preparation used, 1,900 Lf./mgm. protein nitrogen. The pattern was developed with anti-toxin absorbed with 'Fe-proteins'

It may be concluded that the culture filtrate of *C. diphtheriae PW*8 contains macromolecular components which differ in the mechanism of origin. The components of fractions ρ and σ are produced at iron concentration optimal for toxin formation and at a concentration which almost completely inhibits toxin production. Fraction *D* appears to be characteristic of culture filtrates of toxigenic strains of *C. diphtheriae* at iron concentration favourable for toxin production. The effect of iron, however, is a complex one, because the inhibition of production of at least three precipitating components, one of which may be identical with the toxin, is simultaneously observed.

The toxic activity of extracellular diphtheria proteins is localized within fraction *D*. However, the asymmetric distribution of the activity within this fraction, as well as the results obtained on electrophoresis in buffers of low ionic strength, clearly demonstrated its heterogeneity[2]. Fraction *D* contains also considerable amounts of glycoproteins, which may be only partially separated as the more mobile borate-separable fraction D_1 on electrophoresis in borate buffers[2]. It seems that an explanation of the part played by different macromolecular components present in the culture filtrate should throw some light on the mechanism of toxin formation.

Formation of 5-Hydroxytryptamine in an Aqueous Solution of 5-Hydroxytryptophan treated with X-rays

IT has been found that 5-HT (5-hydroxytryptamine) is formed by the action of ultra-violet irradiation on 5-HTP (5-hydroxytryptophan) aqueous solution, as a result of a decarboxylation process[1]. It is of interest to investigate whether the same process takes place under the influence of X-irradiation.

An aqueous 0·1 per cent solution of 5-HTP as a pure base, contained in a 'Pyrex' glass vessel, was irradiated with X-rays generated from a Philips machine, operating at 200 kV. and 20 m.amp. (The glass vessel was in close contact with the target.) The dose-rate was 1,818 r./min., measured by the ionization chamber. The solution was prepared in re-distilled water and exposed to X-irradiation for 10 hr. The thickness of the solution layer was 5 mm. The loss of water caused by evaporation during the exposure time was compensated every 2 hr. The irradiated solution was tested for 5-HT on atropinized œstrous rat uterus[2].

After the irradiation of the solution a brown coloration was noticed. This brown solution showed an oxytocic activity. In preliminary experiments oxytocic activity of the starting material (5-HTP) was examined and we found that 5-HTP *per se* possesses a slight activity on rat uterus, the sensitivity threshold being 0·2 mgm./ml. We were obliged, therefore, to work with the starting solution diluted below this threshold concentration of 5-HTP. After eliminating the interference with 5-HTP, we found that the solution still showed oxytocic activity. The inhibition experiments with lysergic acid diethylamide—a specific antagonist of 5-HT—showed that this activity is to be ascribed to 5-HT. The concentration of 5-HT in the irradiated solution was found to be rather low (0·004 per cent), the *G*-value being 0·2.

Preliminary analysis of descending paper chromatography of the irradiated solution (solvent system: butanol–acetic acid–water (4 : 1 : 5); Ehrlich's reagent) showed, besides 5-HTP ($R_F = 0·30$), four more spots with the following R_F values: 0·12; 0·36; 0·46 and 0·75. The spot with the R_F value of 0·46 corresponded to 5-HT in location, but not in colour.

It has been demonstrated that, in X-irradiated aqueous solutions of histidine[3] and probably tyrosine[4], decarboxylation occurs to a very low amount. This is possible, because in aromatic amino-acids there are a number of sites to be attacked by the free radicals produced from the water. Our results with rather small G-value indicate that 5-HTP (an aromatic amino-acid too) behaves similarly.

It has been noted[5] that 5-HT in aqueous solution undergoes many changes in its structure under the influence of different oxidizing agents. Taking into account the low conversion-rate of 5-HTP to 5-HT, one should consider the possibility of transformations of 5-HT molecules when under the influence of X-irradiation. It seems to us likely that the low amount of 5-HT formed could be partly explained by the action of the various oxidizing species produced by the X-rays.

We wish to thank Dr. A. J. Swallow, London, for his interest and helpful suggestions. 5-HTP was kindly supplied by the National Drug Company, Philadelphia, Pennsylvania.

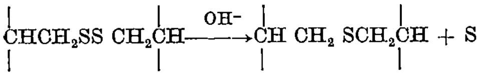
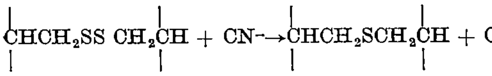
Lanthionine Formation in Keratin

Reaction of wool keratin with solutions of alkalis or potassium cyanide leads to the elimination of one of the sulphur atoms of the dithio bond of the cystine residues with the formation of a thioether (lanthionine) linkage:



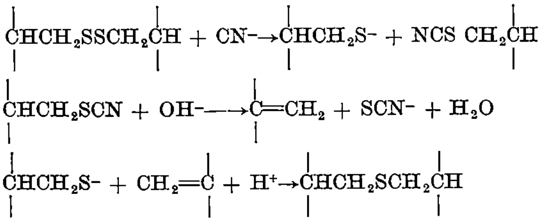
$$\underset{|}{\overset{|}{\mathrm{C}}}\mathrm{HCH_2SS\,CH_2}\underset{|}{\overset{|}{\mathrm{C}}}\mathrm{H} \xrightarrow{\mathrm{OH^-}} \underset{|}{\overset{|}{\mathrm{C}}}\mathrm{H\,CH_2\,SCH_2}\underset{|}{\overset{|}{\mathrm{C}}}\mathrm{H} + \mathrm{S} \qquad (1)$$



$$\underset{|}{\overset{|}{\mathrm{C}}}\mathrm{HCH_2SS\,CH_2}\underset{|}{\overset{|}{\mathrm{C}}}\mathrm{H} + \mathrm{CN^-} \rightarrow \underset{|}{\overset{|}{\mathrm{C}}}\mathrm{HCH_2SCH_2}\underset{|}{\overset{|}{\mathrm{C}}}\mathrm{H} + \mathrm{CNS^-} \qquad (2)$$

It is considered that the reaction with cyanide ions, which overall may be represented by equation (2), can follow two possible courses:

(a)

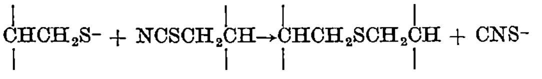


$$\underset{|}{\overset{|}{\mathrm{C}}}\mathrm{HCH_2SSCH_2}\underset{|}{\overset{|}{\mathrm{C}}}\mathrm{H} + \mathrm{CN^-} \rightarrow \underset{|}{\overset{|}{\mathrm{C}}}\mathrm{HCH_2S^-} + \mathrm{NCS\,CH_2}\underset{|}{\overset{|}{\mathrm{C}}}\mathrm{H}$$

$$\underset{|}{\overset{|}{\mathrm{C}}}\mathrm{HCH_2SCN} + \mathrm{OH^-} \longrightarrow \underset{|}{\overset{|}{\mathrm{C}}}\mathrm{{=}CH_2} + \mathrm{SCN^-} + \mathrm{H_2O}$$

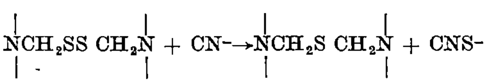
$$\underset{|}{\overset{|}{\mathrm{C}}}\mathrm{HCH_2S^-} + \mathrm{CH_2{=}}\underset{|}{\overset{|}{\mathrm{C}}} + \mathrm{H^+} \rightarrow \underset{|}{\overset{|}{\mathrm{C}}}\mathrm{HCH_2SCH_2}\underset{|}{\overset{|}{\mathrm{C}}}\mathrm{H}$$

(b)



$$\underset{|}{\overset{|}{\mathrm{C}}}\mathrm{HCH_2S^-} + \mathrm{NCSCH_2}\underset{|}{\overset{|}{\mathrm{C}}}\mathrm{H} \rightarrow \underset{|}{\overset{|}{\mathrm{C}}}\mathrm{HCH_2SCH_2}\underset{|}{\overset{|}{\mathrm{C}}}\mathrm{H} + \mathrm{CNS^-}$$

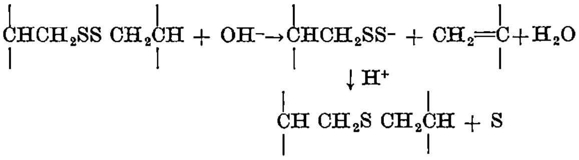
The β-elimination reaction (*a*) was first proposed by Swan[1], who later suggested the possibility of lanthionine formation by SCN- displacement[2] without removal of β-hydrogen atoms. This was confirmed by Earland and Raven[3], who studied the reaction of N-mercaptomethylpolyhexamethyleneadipamide disulphide with cyanide ions, and showed that a thioether bond is formed under conditions identical to those which produce lanthionine in wool:



$$\underset{|}{\overset{|}{\mathrm{N}}}\mathrm{CH_2SS\,CH_2}\underset{|}{\overset{|}{\mathrm{N}}} + \mathrm{CN^-} \rightarrow \underset{|}{\overset{|}{\mathrm{N}}}\mathrm{CH_2S\,CH_2}\underset{|}{\overset{|}{\mathrm{N}}} + \mathrm{CNS^-}$$

Since β-elimination is impossible, it must be concluded that a reaction such as (*b*) is very probably an important route for lanthionine formation in wool.

On the other hand, in the alkaline reaction, Swan[4] has shown the importance of a β-elimination mechanism:



$$\underset{|}{\overset{|}{\mathrm{C}}}\mathrm{HCH_2SS\,CH_2}\underset{|}{\overset{|}{\mathrm{C}}}\mathrm{H} + \mathrm{OH^-} \rightarrow \underset{|}{\overset{|}{\mathrm{C}}}\mathrm{HCH_2SS^-} + \mathrm{CH_2{=}}\underset{|}{\overset{|}{\mathrm{C}}} + \mathrm{H_2O}$$

$$\downarrow \mathrm{H^+}$$

$$\underset{|}{\overset{|}{\mathrm{C}}}\mathrm{H\,CH_2S\,CH_2}\underset{|}{\overset{|}{\mathrm{C}}}\mathrm{H} + \mathrm{S}$$

since $\alpha\alpha'$dimethylcystine is degraded only extremely slowly under these conditions, compared with free cystine.

The reaction of N-mercaptomethylpolyhexamethyleneadipamide with alkalis has now been examined, as it is probably a better model for wool[5] than Swan's compounds, in that the reaction, as with wool, is heterogeneous, giving the ruptured disulphide residues a greater chance to re-unite in a lanthionine linkage.

2·00 gm. of disulphide (sulphur, 4·20 per cent) were boiled under reflux for 5 hr. with 400 ml. of the solution of alkali. After reaction, the solid product was collected, washed with water and dried *in vacuo*. The results obtained are given in Table 1. The analytical methods used have been described previously[3].

Table 1

Solution	pH	Wt. loss (per cent)	Sulphur in product (per cent)	Disulphide sulphur (per cent)	NH_2 m.equiv. 100 gm.
—	—	—	4·20	4·07	1·5
0·10 M Na_2HPO_4	8·0	1·0	3·99	4·26	1·5
0·05 M $Na_2B_4O_7$	9·2	0	4·14	4·27	1·6
0·10 M Na_2CO_3	10·5	2·5	3·70	3·94	2·3
0·10 M Na_2CO_3*	10·5	11·0	3·39	3·28	2·7
0·10 M NaOH	12·0	35·0	2·23	1·90	4·7

* Boiled for 10 hr.

It is shown that a lanthionine type of reaction does not occur when the β $>$CH group is replaced by nitrogen, which must be regarded as strong supporting evidence for the β-elimination mechanism, and against mechanisms which involve formation by direct attack on the α-carbon atom[6].

We thank the Wool Textile Research Council for financial assistance with this work.

Effect of Polyamino Carboxylic Acids on Catalase

CATALASES are known to be inactivated by the formation of compounds with cyanide[1], azide and hydroxylamine[2], so we thought it probable that the iron of the enzyme could be complexed with chelating agents, the effect being also to inactivate the enzyme. The chelating agents used were ethylenediamine tetraacetic acid (EDTA), cyclohexanediamine tetraacetic acid (CDTA), diethylenetriamine pentaacetic acid (DTPA) and NN′ethylene*bis*(2{*o*-hydroxyphenyl}) glycine (EHPG). The rate of decomposition of hydrogen peroxide by bovine-liver catalase in the presence of each of the above chelating agents was followed by a rapid titration method.

A decrease in the rate of destruction of hydrogen peroxide by the catalase was observed in the presence of all the chelating agents. With EDTA and DTPA, the inhibition reaches a maximum at a *p*H of about 8·5 and then decreases again with increasing *p*H. With CDTA, the inhibition increases slowly with increasing *p*H, whereas with EHPG the increase is rapid, although measurements could not be made at *p*H values greater than 10 due to a rapid decrease in the activity of the catalase, probably due to protein denaturation. In conclusion, it must be noted that the inhibition of catalase by these chelating agents is small compared to that of hydrogen cyanide, which has a value of K_i of $4{\cdot}6 \times 10^{-6}$ *M* at *p*H 7 (ref. 3), whereas at *p*H 8·5 (*p*H of maximum inhibition of catalase in the presence of EDTA and DTPA) the K_i values are $9{\cdot}2 \times 10^{-2}$ *M*, $9{\cdot}3 \times 10^{-2}$ *M*, $2{\cdot}6 \times 10^{-1}$ *M*, and $3{\cdot}3 \times 10^{-1}$ *M* for EDTA, DTPA, CDTA and EHPG respectively.

Dextransucrase *V* and the Role of Metal Ions in Enzyme Catalysis

DEXTRANSUCRASE is a representative member of the general class of enzymes known as transglycosidases. In this particular example, the glucosyl group from sucrose is transferred to a suitable acceptor, which causes chain initiation, and dextran is formed. Polymer-formation is governed by many factors such as the nature of the acceptor molecule, *p*H and temperature[1].

This work was directed at the role of metal ions in enzyme catalysis[2]. This was initiated by some previous work which had suggested that magnesium plays a part in dextran synthesis[3,4]. These investigations had shown that a relatively linear molecule of dextran could be isolated from a magnesium-deficient diet inoculated with *Betacoccus arabinosaceous* (Birmingham). This is contrasted with the branched dextran isolated from a normal medium. With this in mind, it was felt important to study the effect of metal ions on the enzyme and to carry out a detailed kinetic investigation.

Using fructose-production as a measure of enzyme activity, the conversion of sucrose to dextran was examined under the influence of several metal cations. The details of the enzyme preparation and the analytical procedures have been reported[2]. In addition to testing the effect of the metal ions on the catalysis, the role of metal chelating agents, tetrasodium ethylenediamine tetraacetic acid (EDTA) and oxalic acid were investigated. All experiments were conducted in a 0·05 *M* acetate buffer of *p*H 5·2 and the reaction was carried out for 0·5 hr. in a constant temperature water bath at 25° C.

Of the metal ions tried as activators of this particular enzyme, notably calcium, zinc, magnesium, manganese and copper, only the first was effective. The reciprocal plot of initial velocity against calcium ion at various substrate concentrations is shown in Fig. 1. From the common intercept of these lines, a value for the dissociation constant of the enzyme metal complex may be evaluated. This turns out to be $9{\cdot}4 \times 10^{-5}$ *M*. The action of EDTA is shown in Fig. 2. The graph for oxalic acid was similar, except

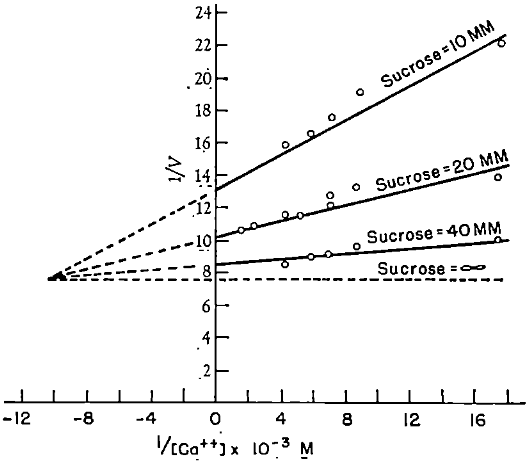

Fig. 1. Reciprocal plot of initial velocity (mgm. fructose/0·2 ml. enzyme/0·5 hr.) against calcium ion concentration. The dashed curve representing sucrose = ∞ was drawn through the intersection of the three other curves and the value for 1/*V* calculated from another experiment using enzyme and sucrose and an excess of calcium ion

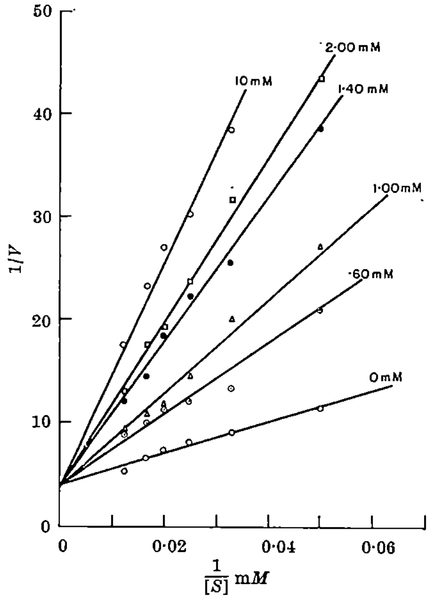

Fig. 2. Reciprocal plot of initial velocity (mgm. fructose/0·2 ml. enzyme/0·5 hr.) against sucrose concentration at various levels of EDTA

that it required twenty-five times as much oxalic acid to achieve the same results.

The plot in Fig. 1 showing the influence of calcium ions fits the first type of coupling activation as described in ref. 5. In this particular case of activation, the substrate will not couple efficiently with the enzyme unless the activator (in this case calcium ion) is already attached to the enzyme. Competitive inhibition is demonstrated in Fig. 2 for the action of the chelating agents. The action of oxalic acid and EDTA appears to be a removal of the calcium ion from the enzyme. This removal renders the catalytic site less active in its action on sucrose. In the presence of excess substrate the influence of the chelating agents is diminished by the law of mass action, as demonstrated by the convergence of the lines in Fig. 2 to a common intercept.

The ability of magnesium ion to influence the degree of branching has been mentioned[3,4]. In view of this fact, it is rather surprising at first sight that magnesium appeared to have no influence on the course of the reaction in this work. A possible explanation for this apparent anomaly might rest on the following argument: according to Bovey[6,7] there are at least two enzymes responsible for the synthesis of dextran. One enzyme operates by initiating chain-growth and liberating fructose. The other, the so-called 'branching enzyme', operates by transferring pre-formed units of oligosaccharides to the main chain. This latter enzyme would not liberate any reducing sugars; consequently it would not be detected by the methods of analysis used in this investigation.

Degree of Polymerization of Hyaluronic Acid isolated from Human Aortic Tissue

SEVERAL reports have been presented on the degree of polymerization of hyaluronic acid isolated from umbilical cords, ovarian cysts and follicular fluid, synovial fluid and vitreous bodies[1-5]. The hyaluronic acid isolated from the tissues mentioned shows varying degree of polymerization.

In a previous publication Bertelsen and Marcker[6] discussed variations in the ratio chondroitin sulphuric acid/hyaluronic acid in aortic tissue with age. In this investigation the degree of polymerization of hyaluronic acid isolated from human aortæ has been determined by means of osmometry.

The aortæ were obtained 12–15 hr. after death. The adventitia was carefully removed by hand, and the media-intima parts of the vessels were stored in acetone for 4–5 months. Owing to the small amount of tissue in children, samples from individuals less than 2 yr. of age were pooled. Furthermore, three groups of aortæ from the new-born were included in the material, each of the groups consisting of 10–12 aortæ. Only macroscopically normal tissue was collected, and so, if the question were about elderly individuals with atherosclerotically changed aortæ, the changed parts were discarded.

The disintegrated, de-fatted tissue was incubated with a proteolytic enzyme, and the protein-split products were precipitated with trichloroacetic acid. The residual protein-split products were removed by repeated shakings with chloroform–*iso*amylalcohol[7] and subsequent dialyses against running tap-water. A more detailed description of the method of extraction was given in ref. 6.

In order to remove the chondroitin sulphuric acids, the aqueous solution of mucopolysaccharides was brought to *p*H 1·5 with 0·1 M hydrochloric acid in the presence of 0·1 M sodium chloride at 0° C. At this *p*H the ionization of the hyaluronate is suppressed, whereas the chondroitin sulphates are largely ionized. 1 gm. of 200–400-mesh amine ion-exchange resin 'Dowex 1–X8' in the chloride form per 25 ml. of the mucopolysaccharide solution was added, and the mixture was stirred for 2 hr. at 0° C. (ref. 8). After removal of the resin by centrifugation and filtration through a glass funnel, the *p*H was raised, and by slowly adding two volumes of cold absolute alcohol, the hyaluronate was precipitated. The precipitate was washed in absolute alcohol and ether and dried in a vacuum desiccator containing silica-gel.

To characterize the isolated substances, we used nitrogen and sulphur determinations, viscometric determinations and subsequent incubation with streptococcal hyaluronidase and paper chromatography. The nitrogen was determined by the micro-Kjeldahl procedure, and the sulphur contents of the hyaluronic acid preparations were determined by the method of Zinneke[9]. Viscometric investigations were performed in the micro-viscometer described in ref. 10. Paper chromatography of hydrolysates of the substances was performed in 2,6-lutidine/water (65 : 35) for 24 hr., and the chromatograms were developed by a 0·1 per cent ninhydrin solution in acetone.

The following tends to show that the isolated substances really were hyaluronate: the white powders were: (1) highly hygroscopic; (2) easily soluble in water, the solutions being clear and viscid; (3) the viscosities decreased considerably after incubation with bacterial hyaluronidase, giving the characteristic degradation curves of hyaluronic acid. Furthermore, (4) the paper-chromatograms of the hydrolysates only showed spots corresponding to authentic glucosamine, and (5) the amount of nitrogen in all samples was about 3·6 per cent (theoretically 3·4). The sulphur in the samples ranged from 0·6 to 0·8 per cent (with one exception), thus indicating only minor amounts of sulphated mucopolysaccharides.

The molecular weights were calculated from colloid osmotic pressure measurements performed by the micro-osmometer described in ref. 2. The concentration used in the osmotic pressure measurements was 5 mgm. of the isolated substance in 1 ml. 0·5 M potassium chloride. According to our experience the influence of the Donnan effect is then negligible.

The results are shown in Table 1. It will be seen that the degree of polymerization of hyaluronic acid in aortic tissue is independent of age and degree of atherosclerosis.

The isolation procedure used in this investigation is generally considered very sparing, and it is unlikely that any significant depolymerization occurred during the isolation.

Table 1. MOLECULAR WEIGHTS (*M*) OF HYALURONATE ISOLATED FROM HUMAN AORTÆ, CALCULATED FROM MEASUREMENTS OF THE OSMOTIC PRESSURES

Age (yr.)	Sex	$M \times 10^3$	Nitrogen (per cent)	Sulphur (per cent)	Gross appearance
0		44	3·62	0·69	No plaques
0		43			No plaques
0		35			No plaques
0·5–2*		51	3·59		No plaques
6	♂	30	3·18	0·63	No plaques
11	♂	48		0·61	No plaques
35	♀	48	4·29		Lipoid plaques
50	♂	43	3·52	0·76	Slight sclerosis
60	♂	47	3·62		Slight sclerosis
63	♀	40		0·73	Pronounced sclerosis
72	♀	42	3·44	1·30	Pronounced sclerosis
84	♂	60	3·80	0·81	Pronounced sclerosis

* This group consists of three aortæ.

Owing to the small amount of substance at our disposal, only some of the results with nitrogen and sulphur have been determined.

The molecular weights presented in Table 1 refer to apparent molecular weights, and not to true molecular weights; the latter, which are obtained by extrapolating to zero concentration, are, therefore, a little higher than those recorded.

It can be concluded that the hyaluronic acid isolated from aortic tissue seems to have a comparatively low molecular weight as compared with the molecular weights obtained for hyaluronic acid isolated from other tissues.

This work was aided by a grant from the Danish State Science Foundation.

Incorporation of Deoxyribonucleic Acid by Mammalian Cells *in vitro*

TRANSFORMATION of bacterial cells in the presence of deoxyribonucleic acid (DNA) has been demonstrated[1-3], and has indicated that genetic information is carried by DNA. There is little unequivocal evidence for such transformations in higher forms of life, in contrast to the obvious transfer of genetic information that occurs by means of the gamete during fertilization. The two reported attempts to obtain these transformations through the mediation of added DNA have been conflicting[4,5]. On the other hand, evidence for the uptake of DNA by mammalian cells[6,7] has supported the idea that observed biological effects might be obtained. In this communication I present evidence for the incorporation of extracellular high molecular weight DNA into the nuclear DNA of cells of the Ehrlich–Lettré ascites tumour, when they are incubated *in vitro* (Table 1). Labelled homologous DNA for these experiments was first obtained by injecting formate labelled with carbon-14 intraperitoneally in mice bearing this tumour. After an appropriate time-interval, the tumour cells were removed and washed and the DNA isolated by the detergent procedure[8]. To determine the specific activity of the DNA used in the experiments, samples were hydrolysed with 70 per cent perchloric acid for 1 hr. at 100° C. and the bases, adenine and thymine, separated by paper chromatography using a solvent system of *iso*propanol, hydrochloric acid and water. The bases were eluted and the specific activity of each was determined for appropriately plated samples using a gas-flow counter for the radioactivity determinations.

Table 1. *In vitro* INCORPORATION OF DNA LABELLED WITH CARBON-14 BY EHRLICH-LETTRÉ ASCITES TUMOUR CELLS

	Specific Activity (counts/min./μmole base) Adenine	Thymine	Ratio adenine : thymine
Initial DNA, from *in vivo* labelling	3,852	1,395	1·00 : 0·36
Nuclear DNA after incubation	296	93	1·00 : 0·31

Incubation conditions: 2 ml. ascites fluid (0·5 ml. packed cells), 1 ml. 0·25 *M* sucrose—0·1 *M* phosphate buffer *p*H 7·4, 0·8 ml. 0·1 *M* glucose in 0·25 *M* sucrose, 0·2 ml. water. Incubated aerobically at 37° C. for 1 hr. in a metabolic shaking incubator.

In the incubation experiments tumour cells were obtained by draining the fluid from an abdominal incision in mice bearing a tumour growth of 7–10 days. The cells were incubated aerobically in a shaking incubator at 37° C. in the presence of ascites serum, 0·25 sucrose–phosphate buffer *p*H 7·4, glucose[9], and with samples of the intact labelled DNA dissolved in the buffer solution. After 1 hr. the cells were washed carefully with the sucrose–phosphate buffer and saline, and were then frozen in a dry-ice/acetone mixture. The frozen cells were homogenized in dilute citric acid (0·05 *M*) and fractionated by differential centrifugation to obtain preparations of clean nuclei. This procedure is of importance to ensure that the observed uptake is in nuclear material. The isolated nuclei were washed several times during the preparation with 0·01 *M* citric acid and were extracted finally with cold 4 per cent perchloric acid and lipid solvents[10]. The dry residual nuclear material was hydrolysed with 0·3 *N* potassium hydroxide for 18 hr. at 37° C. to separate the nuclear ribonucleic acid (RNA). DNA was obtained by acidifying the alkaline hydrolysate and extracting the residue with 4 per cent perchloric acid at 90° C. for 15 min. The DNA fraction was dried, then hydrolysed with 70 per cent perchloric acid as before and the bases separated by paper chromatography using the solvent system described.

The amount of DNA taken up by the nuclei under these conditions can be calculated from the total number of counts added before, and obtained after, the incubation. In these experiments it has been found that there is an observed uptake of 2–4 per cent of the added DNA by the nuclei of these cells. In looking further, in an examination of the specific activity of the nuclear DNA, it has been found that despite an expected dilution the ratio between the specific activity of adenine and thymine is similar to that of the original sample of DNA used in the experiments. While it is recognized that these observations might be explained by assuming a prior breakdown of the DNA followed by its re-synthesis in the cell nucleus, this seems unlikely, because of the difference in the degree of labelling of the bases adenine and thymine of DNA, under *in vivo* and *in vitro* conditions (to be described elsewhere). It is concluded that some intact extracellular DNA of high molecular weight can be transferred across the cell and be incorporated into the genetic fine material of these cells. Further attention is being directed to the conditions necessary for this transfer and incorporation and to the biological effects elicited by such incorporation.

This research has been supported by a grant (C–5172) of the National Cancer Institute of the U.S. Public Health Service.

Anticancer Properties of Thio-diglycollic Acid

In earlier publications[1–4] we have shown possibilities of preferential inhibition of tumour growth by antimetabolites of hexose monophosphate (HMP) pathway. A number of derivatives of thiophene-dicarboxylic acid have been prepared and tested for their anticancer properties. Results with thiophene 2,5 dicarboxylic acid (TDA) and 2,5 dicarbethoxy-3,4 dihydroxy thiophene (DICETOL) have already been published[3,4]. Results with other compounds will be published in detail elsewhere. One of the compounds synthesized in this series was thio-diglycollic acid (TDGA). In this compound carbon numbers 3 and 4 from thiophene have been completely dispensed with. This, in a way, amounted to an attempt to identify the active groupings which may be responsible for the anticancer properties.

Thio-diglycollic acid was synthesized by treating mono-chloro acetic acid with sodium sulphide, as described by Barkenbus and Landis[5]. This compound is extremely soluble in water. It was therefore isolated from aqueous solutions by continuous liquid-liquid extractions with ether.

Table 1. Analytical Data

Calculated	C = 32·00 per cent	H = 4·00 per cent
Found	C = 31·50 per cent	H = 3·60 per cent
Melting point:	Literature, 129°;	Found, 129–131°

The anticancer property of this compound was tested against two transplantable tumours: (1) Yoshida sarcoma (ascites) in rats and (2) solid fibrosarcoma in Swiss mice[6].

Thirty-six Wistar female rats, 2·5–3 months old, were transplanted intraperitoneally, under aseptic conditions, with 0·6 ml. each of freshly withdrawn Yoshida sarcoma ascitic fluid. After 8 hr., the animals were randomly divided into two groups—control and experimental—of 18 animals each. Control animals received 0·5 ml. of isotonic saline, while the experimental animals were given 2 mgm. of TDGA dissolved in 0·5 ml. of isotonic saline intraperitoneally. The treatment was given three times a day, with a total dose of 6 mgm. of TDGA/rat/day (40 mgm./kgm. of body weight). Multiple daily injections were necessary to maintain adequate drug concentration at the tumour site throughout the day. All the rats from the control group died between the fourth and ninth day after transplantation. TDGA administration to the experimental group was discontinued after the tenth day and survival observed. Out of the eighteen animals only two animals died 35 days after transplantation with solid growth in the peritoneal cavity. The remaining sixteen rats from the experimental group have survived for more than 5 months after transplantation, even though the drug administration was discontinued on the tenth day (Fig. 1). Since Yoshida sarcoma is a very rapidly growing tumour, it was anticipated that, even if a few viable cells had been left behind, the tumour growth would have flared up and killed all the transplanted animals within 10 days after discontinuation of the treatment. But the fact that sixteen out of eighteen animals have survived for more than 5 months after the discontinuation of the treatment suggests that Yoshida sarcoma tumour cells have been completely wiped out by TDGA treatment. All the animals from the experimental group are normal and do not show any toxic side-effects. The animals are still under observation.

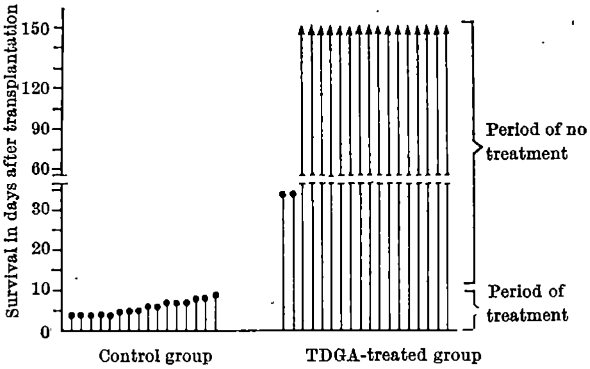

Fig. 1. Effect of TDGA on survival of Yoshida sarcoma (ascites) bearing rats. ●, Rats dead; ▲, rats living

TDGA is an acidic substance which was directly injected into the peritoneal cavity. In an auxiliary experiment, acetic acid in similar concentration was injected in the peritoneal cavity of Yoshida sarcoma-bearing rats and survival observed. It was found that the animals treated with acetic acid died more or less at the same time as the control group, suggesting that the therapeutic effects observed with TDGA were not due to acidity of the substance.

Influence of TDGA was also studied on transplantable solid fibrosarcoma in Swiss mice[6]. For this purpose, fibrosarcoma was implanted by subcutaneous injections of 0·5 ml. of tumour suspension, and the treatment started after the thirteenth day when the tumour attained measurable and uniform size in all the animals. TDGA was injected subcutaneously twice a day and the total daily dose was 6 mgm./day (240 mgm./kgm. of body weight). The animals were killed after 12 days treatment (twenty-fifth day after transplantation). The results are shown in Table 2. It will be seen that, although the results with solid fibrosarcoma were not as spectacular as with Yoshida ascites tumour, there was definite evidence of inhibition of tumour growth. The average weight of tumour from the control animals was 4·75 gm. as against 2·8 gm. in the TDGA-treated animals.

TDGA did not show any toxic side-effects with the therapeutic doses employed. Large amounts of

Table 2. EFFECT OF THIO-DIGLYCOLLIC ACID (TDGA) ON GROWTH OF FIBROSARCOMA IN SWISS MICE*

Treatment	Dose	Day of treatment after transplantation	Period of treatment (days)	Average tumour weight and range (gm.)
Treated	6 mgm./day	13th	12	2·829 (1·470–3·628)
Control	—	13th	12	4·755 (4·378–6·273)

* 6–8 weeks old Swiss female mice were used in these experiments.

TDGA, at a dose of 1,250 mgm./kgm. body-weight, were injected at one shot subcutaneously. Except for the skin necrosis seen at the site of injection, the treated animals did not show any toxic side-effects. Further work on the mechanism of action is in progress. TDGA has two acidic groups, and hence, in addition to studying its role as an antimetabolite of pentose phosphate pathway intermediates, its action as a potential bifunctional group is also under investigation.

HISTOCHEMISTRY

Muscle Target Fibres, a Newly Recognized Sign of Denervation

THE muscle target fibre, a newly recognized sign of skeletal muscle fibre denervation, as observed in muscle biopsies from patients with neuromuscular disease, is described in this communication. From a series of forty-six biopsies showing the classic features of denervation[1] (associated with a variety of diseases), 27 specimens also contained target fibres. Eight specimens had 3–10 target fibres, four had 10–20 target fibres, and fifteen had more than twenty target fibres. The presence of target fibres could not be correlated with any particular associated disease. A concurrent series of 25 muscle biopsies showing the classic features of myopathy[1], associated with a variety of diseases, did not contain any target fibres. A concurrent series of 29 muscle biopsies having no pathological features did not contain any target fibres.

The name 'target fibre' is derived from the appearance on cross-section (Figs. 1*a*, 2*a*, *b*). Each muscle fibre so affected has three more or less distinct concentric zones, numbered 1, 2, and 3 from the centre outward, although these is some variability in this pattern. Occasionally zone 2 is absent. More than one target within a fibre is rare. On longitudinal section through the centre of the target fibre, five parallel-bordered zones appear (from one side to the other—3, 2, 1, 2, 3), running the length of the fibre present on the slide (Fig. 1*b*). In paraffin-embedded sections, target fibres are best demonstrated after fixation in Bouin's fluid and staining by the phosphotungstic acid hæmatoxylin or the Gomori trichrome method.

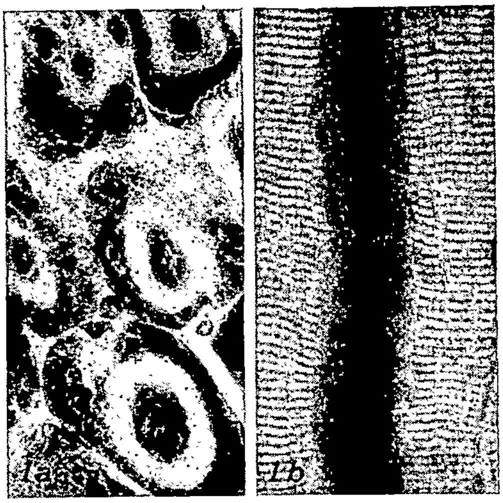

Fig. 1. *a*, Phosphotungstic acid hæmatoxylin stain (× 560); *b*, Gomori trichrome stain, polarized light. The anisotropism of zone 1 is masked by the stain (× 560)

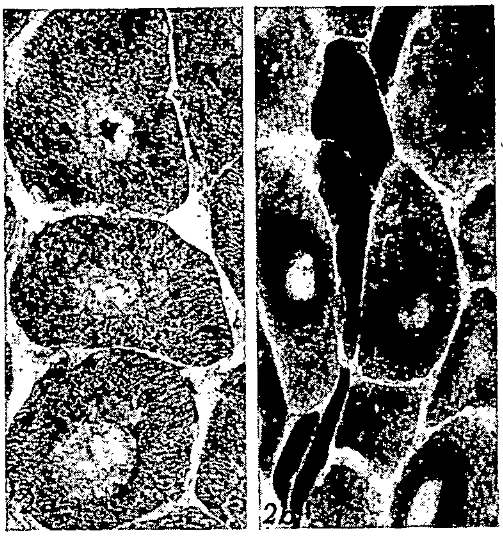

Fig. 2. *a*, Lactate dehydrogenase (× 225); *b*, alkaline adenosine triphosphatase (× 225)

Zone 1, in paraffin sections (Figs. 1*a*, *b*), contains compact wavy longitudinally running strands of myofibril-like material, which lack cross-striations and are uniformly anisotropic in polarized light. In fresh frozen sections, histochemical evidence of mitochondrial oxidative enzyme activity (succinate dehydrogenase[2], lactate dehydrogenase, cytochrome oxidase[3]) is completely absent (Fig. 2*a*). Evidence for the presence of glycogen (periodic acid–Schiff stain), for the means of glycogen formation (glucose-1-phosphate + uridine triphosphate via uridine-diphosphate-glucose to glycogen[4]), or for the means of glycogen breakdown (amylophosphorylase reaction[5]), which are sarcoplasmic reactions, is completely absent. Alkaline adenosine triphosphatase activity[6] is absent (Fig. 2*b*). In a few instances, within zone 1 there is a small region of high activity of the oxidative enzymes (Fig. 2*a*), the glycogen metabolism enzymes, and the periodic acid–Schiff reaction.

Zone 2 appears virtually unstained in paraffin sections. The concentration of myofibrillar material appears reduced, but there is a faint normal cross-striated pattern detectable in polarized light. Alkaline adenosine triphosphatase activity is increased. The mitochondrial oxidative enzyme reactions are usually decreased or absent, but infrequently they may be increased. The reactions associated with glycogen metabolism may be increased or decreased.

Zone 3 usually appears normal by all the methods used.

In the target fibres, the nuclei are not abnormal in appearance or location. There is not an increase of connective tissue or an inflammatory cell reaction around the target fibres. The target fibres are either of about normal diameter or are somewhat smaller than normal. They may appear in a group suggesting a motor unit, but such a pattern cannot always be determined, especially when their number is small or very large.

One must distinguish target fibres from the muscle fibres containing central cores in central core disease[7–9]. The central core fibres differ from target fibres in the following features: the central core, in paraffin sections or after histochemical staining, appears as a central uniform region (or regions) within the muscle fibre. With nearly all the ordinary histological techniques, the central core is more darkly stained than the surrounding non-core region. On longitudinal section, the central core has well-preserved cross-striations. There are no classic features of denervation in the muscle of central core disease, but there infrequently may be features of an active myopathy[9].

The work described here indicates that the target fibre represents a pathological alteration of the cyto-architecture of the human skeletal muscle fibre, which has been found only in association with denervation. It is concluded that the target fibre is a sign of skeletal muscle denervation. As the target appearance occurs in fibres of normal or somewhat smaller than normal diameter, it probably signifies recent denervation.

Most of the muscle biopsies reviewed were generously provided by Dr. G. Milton Shy. Prof. W. Blackwood kindly permitted study of the specimen shown in Fig. 1*a*.

RADIOBIOLOGY

Assessment of Chronic Exposure to Radiostrontium by Urinary Assay

RADIOACTIVE contamination of the biosphere and particularly of the human population is a contemporary problem of high interest, and strontium-90 is perhaps the most important single radionuclide concerned. We require to know what levels are being incorporated into the human population at any given time. Since food is the major route by means of which environmental radiocontaminants reach human beings, attention has largely been turned to the monitoring and surveying of food and water. This communication proposes that urinary assays of strontium-90 and calcium may have considerable advantage for the estimation of the contemporary strontium-90 to calcium ratio of the intake, and for estimation of the strontium-90 to calcium ratio in newly forming bone. The same considerations would also apply to strontium-89 whenever this radionuclide is of inportance.

Several investigations have shown that, under typical conditions, the strontium to calcium ratios between diet, various tissues and secretions are roughly constant. Examination of results obtained by independent methods in many laboratories and countries has indicated that under usual dietary conditions the values of the ratio (strontium/calcium of sample (ref. 1)) to (strontium/calcium of precursor), called here the 'observed ratio', fall within a reasonably narrow range, with few indications of variations as high as a factor of 2. Some typical values are as follows: observed ratio (body/diet) for human beings, 0·25–0·50 (refs. 2–4); observed ratio (body/diet) for cattle, sheep, pigs, goats, 0·2–0·25 (refs. 2 and 5); observed ratio (milk/diet) for human beings, cow and goat, 0·09–0·16 (refs. 2 and 4).

An example of the usefulness of this concept is the estimation of the comparative levels of strontium-90 and calcium in the total dietary intake of dairy cattle by calculation from values in milk. There seems little question but that dividing the ratio strontium-90/calcium in milk by 0·1 (typical value for observed ratio (milk/diet)) would give an estimate of dietary intake more simply and more accurately than would efforts to measure total intakes directly or to sum the strontium-90 and calcium contributions of components of the feed and water. Also, an estimate of the strontium-90/calcium being laid down in the newly forming and exchangeable bone of the animals could be obtained by dividing this ratio in milk by 0·5 (typical value for observed ratio (milk/plasma)).

It is well known that urinary calcium excretion is highly variable between individuals and even from day to day in the same individual. It is assumed that urinary strontium would also be variable. Since many of the factors that affect the behaviour of calcium also affect that of strontium in the same way, there is the likelihood that variations would be smoothed by using the strontium–calcium ratio as the basis of measurement.

Table 1 presents results from experiments with rats designed to show the variation of the observed ratio (urine/diet) with time following the start of ingestion. In Experiment 1, 8 rats of about 80 gm. body-weight were placed in metabolism cages and fed commercial rat pellets; the drinking water throughout the work was labelled with calcium-45 and strontium-85 for double-tracer studies according

Table 1. STRONTIUM–CALCIUM RELATIONSHIPS BETWEEN DIET AND URINE OF RATS

Experiment	Time after start of dosage	Observed ratio (urine/diet)*
1	17 hr.	2·6 ± 0·97†
	41 ,,	2·8 ± 0·72
	64 ,,	3·2 ± 0·55
	88 ,,	3·0 ± 0·52
	12 days	3·3 ± 0·53
	24 ,,	2·8 ± 0·28
	35 ,,	4·1 ± 0·20
		Average 3·1
2	14 days	3·2 ± 0·37‡

* Observed ratio = Sr*/Ca* in urine ÷ Sr*/Ca* in diet.
† Mean ± standard error of mean of 8 animals.
‡ Mean ± standard error of mean of 22 animals.

to usual procedures[6]. It is noted that a statistically constant value of observed ratio (urine/diet) had been reached by 17 hr. after the start of ingestion of the radionuclides. In Experiment 2, 22 rats were used ranging in body-weight from 80 to 500 gm.; a mean value is reported since no significant differences were noted between age-groups. This work shows that urine values in rats do reflect intake of the previous few days, and that the variability was not excessive as shown by the values for the standard error of the mean.

It is next of interest to examine the literature for values of observed ratio (urine/diet) for human beings in normal health. Two investigations have been reported in which the stable strontium and calcium of normal diets and urine were estimated[7,8]. From other work as yet unpublished, Dr. Herta Spencer of the Montefiore Hospital has made available some results of fall-out strontium-90 and stable calcium in the diets and urine of several individuals; in this series, three 6-day balance trials were run on each individual and the averages are reported. It is seen from Table 2 that, in 16 individuals of 4–64 years, the range of observed ratio (urine/diet) was 0·43–1·1 with a mean of 0·67 ± 0·058; the variability was about the same as in the work on rats. The average value of 0·67 is in agreement with the typical values of observed ratio (body/diet) about 0·25 and observed ratios (urine/plasma) about 3 (ref. 7). Thus an estimate of the strontium-90 to calcium of the total diet would be obtained from the measured strontium-90/calcium of the urine divided by the observed ratio (urine/diet), typical value 0·67 ; an estimate of the strontium-90 to calcium being laid down in the skeleton would be obtained by the strontium-90/calcium of the total diet multiplied by the observed ratio (body/diet), typical value 0·25.

Table 2. STRONTIUM–CALCIUM RELATIONSHIPS BETWEEN DIET AND URINE OF HUMAN BEINGS

M	50 yr.		0·40	7
F	18 yr.	(fall-out strontium-90 and stable calcium in urine and diet)	1·1	10
F	19 yr.		0·43	10
F	19 yr.		0·64	10
M	21 yr.		0·44	10
F	28 yr.		0·93	10
F	29 yr.		0·94	10
F	64 yr.		0·45	10
		Mean ± standard error of mean	0·67 ± 0·058	

Additional work is needed to get better measures of variability and of the effects of unusual diets, age or other factors that might modify the value of observed ratio (urine/diet). For example, it has been shown that new-born babies apparently have considerably higher values of observed ratio (urine/diet)[9]. In any event, it would appear feasible to collect enough urine samples (from the same individual and/or from different individuals) to give results of quite sufficient accuracy for purposes of food monitoring. The lower the contribution of food contamination relative to the total radiation exposure of the population, the lower the accuracy needed for assessment. Since present exposures from strontium-90 are only a few per cent of exposures from natural background, there would seem little need to evaluate food contamination with an accuracy much greater than appears to be possible from urinary surveys.

The advantages of using urinary assays are listed as follows : (*a*) the urinary samples reflect the total amount of strontium-90 and calcium that enters body tissues, and there is no need to guess the contributions of given food items or the availability of the strontium-90 in given food items; (*b*) values are calculated in terms of total strontium-90 and total calcium in the intake, which is probably the most important parameter governing the body burden ; (*c*) any sudden changes in levels of strontium-90 would be noted early, and the results could reflect any day-by-day variations; (*d*) sampling and bulking would be relatively simple and work could be designed to reflect individual intakes as well as group averages classed according to any category of interest ; (*e*) the results could be interpreted to give values for concentrations of strontium-90 and strontium-90/calcium ratios in areas of newly forming and exchangeable bone ; (*f*) from a continued programme of sampling it would be possible to construct the time pattern of radiostrontium-levels in bone.

Monitoring of food supplies by urinary assays would not eliminate the need for the examination of foods themselves, to obtain an understanding of the factors that govern the movement of radio-strontium in the food chain.

This investigation was supported by the U.S. Atomic Energy Commission: it was mentioned at an information meeting of the Commission last autumn.

Metabolism of the Sulphur Amino-Acids and of Sulphate in *Blattella germanica*

THE cockroach and the Japanese beetle are able to utilize sulphate-S for the synthesis of methionine and cystine[1]. The German cockroach, *Blattella germanica* (L.), is also able to satisfy its sulphur requirements with homocystine, methionine sulphoxide, cysteic acid, taurine, and β-hydroxyethanesulphonic acid[2]. However, removal of the intracellular symbionts from the cockroach prevents incorporation of sulphate-S into cysteine and methionine[3].

The present communication describes the results obtained when ^{35}S-methionine, ^{35}S-cystine, and their oxidation products were administered to xenic (symbionts and intestinal micro-organisms present) and aposymbiotic *Blattella*. Further developments in the study of the metabolism of ^{35}S-sulphate are also described.

One to five microcuries of the ^{35}S-compound were injected into the insects, which were then maintained at 25° C. for one to seven days. They were then homogenized in 80 per cent v/v ethanol and the distribution of ^{35}S-components in the extracts and in hydrolysates of the residues was investigated. The results are summarized in Table 1.

The approximate distribution of the radioactivity in the known compounds is indicated by the number of plus signs. The results show that: (1) Cystine and cysteine were rapidly converted to glutathione, taurine, and sulphate by both xenic and aposymbiotic *Blattella*, but conversion of cysteine to methionine occurred only in xenic *Blattella*. (2) Cysteic acid was decarboxylated to taurine and oxidized, to a small extent, to sulphate by both xenic and aposymbiotic insects. (3) Most of the taurine is excreted unchanged. However, when intestinal bacteria are present, some of the taurine is degraded to sulphate, which may then be used by the xenic cockroach for the synthesis of cystine. (4) Sulphate sulphur is incorporated into cystine, methionine, taurine, sulphite, and various unidentified compounds by xenic *Blattella* but only sulphite and unidentified substances are formed by the aposymbiotic insect[3]. In contrast to the chick embryo xenic *Blattella* forms only a barely detectable amount of ^{35}S-taurine after $Na_2{}^{35}SO_4$ administration. This suggests that, in the cockroach, taurine is not formed directly from sulphate, but via cysteine. The reduction of sulphate to sulphite, which is widespread in plants and micro-organisms, occurs in the cockroach and, to our knowledge, only in the vitellin sac of the chick embryo[4]. (5) Methionine and methionine sulphoxide appear to be completely interconvertible by both xenic and aposymbiotic *Blattella*. A small quantity of CH_3SH, but no hydrogen sulphide or cysteic acid, was produced by the insects injected with methionine. (6) The sulphur of methionine sulphone was not detected in any other compound after its administration.

Cysteic acid has been proposed by a number of workers as an important intermediate in sulphur metabolism. As cysteic acid was not found in extracts of cockroaches after feeding or injection of sulphate, cystine, cysteine, methionine, or methionine sulphoxide, it does not seem to be a significant intermediate in *Blattaria*.

The results indicate that methionine and cystine are converted in the cockroach to sulphate by at least two pathways: (*a*) methionine sulphoxide ⇌ methionine → (homocysteine) → (cystathionine) → cysteine → (cysteinesulphinic-acid) → β-sulphinyl pyruvic acid → sulphite → sulphate; or (*b*) methionine → (homocysteine) → (cystathionine) → cysteine → (cysteinesulphinic-acid) → (2-aminoethane sulphinic acid) → taurine → ? → sulphate. Pathway *a* for the oxidation of cysteine is characteristic of most organisms and is probably the principal method of sulphate production in the cockroach.

In order to show that the results obtained with the aposymbiotic cockroaches were not due to traces of aureomycin carried over from the maternal diet, normal *Blattella* nymphs were placed on the aureomycin diet several days prior to cystine-^{35}S administration and caged in aureomycin-coated flasks. No inhibition of trans-sulphuration occurred as a result of this treatment.

The hypothesis that the intracellular symbionts are responsible for converting sulphate-S into methionine-S–cystine-S was substantiated by feeding *Blattella* nymphs a diet containing 0·1 per cent aureomycin until they matured. The adult insects, devoid of intestinal bacteria but retaining the intracellular symbionts, incorporated sulphur-35 from $Na_2{}^{35}SO_4$ into methionine, etc.; but their aposymbiotic progeny were unable to utilize sulphate for amino-acid synthesis even after re-establishment of the gut microflora.

Table 1. RADIOACTIVE METABOLITES OBSERVED IN THE ALCOHOLIC EXTRACTS OF *Blattella germanica* AFTER INJECTION OF VARIOUS COMPOUNDS LABELLED WITH SULPHUR-35

Physiological condition of insect	Compound injected	Metabolites into which sulphur-35 was incorporated					
		Cysteine	Glutathione	Methionine + methionine sulphoxide	Sulphate	Taurine	Unidentified compounds
Xenic	Cyst(e)ine	+++	+++	+++	+++	++	Present

Aposymbiotic		+	+	+++	++	–	,,
Xenic	Methionine sulphone	–	–	–	–	–	Absent
Aposymbiotic		–	–	–	–	–	,,

The effect of temperature on sulphate utilization in xenic cockroaches was studied. Two unidentified compounds were produced in greater quantities at 5° C. while a third, which was almost absent at 5° C., accounted for about 10 per cent of the total radioactivity of the ethanol extract when the animals were maintained at 20 to 25° C. A chloroform extract of cockroaches which had been injected with sulphate-^{35}S and held at temperatures above 15° C. contained another unidentified radioactive compound, possibly a sulpholipid. Acid hydrolysis of this compound yields sulphate. Cystine and methionine were not formed at 5° C.

This work was supported in part by Grant-*E*-2608 (*C*-1) of the National Institutes of Health, U.S. Public Health Service.

PHYSIOLOGY

Selective Uptake of Specifically Bound Cobalt-58 Vitamin B_{12} by Human and Mouse Tumour Cells

Many body fluids have been reported to contain substances that combine with vitamin B_{12}. However, research concerning the role of these substances in the absorption of vitamin B_{12} by animal cells has been confined mainly to work involving intrinsic factor preparations or normal human gastric juice. A large amount of evidence has led to general acceptance that vitamin B_{12} bound to intrinsic factor is taken up by intestinal mucosa cells to a greater extent than unbound vitamin B_{12} (ref. 1). Intrinsic factor also has been shown to promote uptake of vitamin B_{12} by rat liver slices[2,3] and liver homogenates[4]. The latter process apparently is not influenced by changes of temperature, and it is not affected by metabolic inhibitors such as 2,4-dinitrophenol[3].

The evidence that human serum may promote uptake of vitamin B_{12} by mammalian tissues remains contradictory. Herbert[3] has reported that the uptake of vitamin B_{12} by rat liver slices is enhanced if the slices are first incubated in the presence of human serum and then incubated in the presence of free vitamin B_{12}. Miller[2], however, was unable to demonstrate a stimulation of uptake of vitamin B_{12} upon incubating rat liver slices simultaneously with human serum and vitamin B_{12}. Several authors have reported that normal human serum may be required for the utilization of vitamin B_{12} by human erythroid cells in tissue culture[5,6], but others have not been able to confirm this finding[7]. We have shown that human serum caused marked stimulation of uptake of vitamin B_{12} by HeLa cells and mouse Ehrlich ascites tumour cells. Enhancement of uptake of vitamin B_{12} by Ehrlich ascites tumour cells was produced also by mouse ascites fluid. These observations led to the further work reported here.

Ehrlich ascites tumour cells were taken from *CF*1 mice seven or eight days after intraperitoneal transplantation. The cells were centrifuged and, after removal of the supernatant ascites fluid, were washed three or four times in cold Krebs–Ringer phosphate solution. The cells then were re-suspended in sufficient Krebs–Ringer solution to yield a 1 : 5 dilution; 0·5 ml. of this suspension per 5 ml. of incubation medium was used. The ascites fluid, filtered through cheesecloth after clotting had taken place, contained 1·8 mμgm., or less, vitamin B_{12} per ml. on assay with *Euglena gracilis*[1].

HeLa cells (generously supplied by Dr. A. M. Masson, Virology Laboratory, McGill University, Montreal) cultured in medium 199 (purchased from Microbiological Associates, Washington, D.C.) containing 20 per cent calf serum were collected six days after sub-culture by shaking in 0·045 *M* ethylenediamine tetraacetate at *p*H 7·4 for 30 min. The cells were washed three times in cold Krebs–Ringer phosphate solution containing 100 mgm. glucose per 100 ml. After re-suspension in Krebs–Ringer solution, approximately 0·2 ml. of packed cells was used per 6 ml. incubation medium. Human serum was obtained from patients with pernicious anæmia in relapse and from patients in the third trimester of pregnancy in order to ensure a low concentration of non-radioactive vitamin B_{12}. The sera used had a vitamin B_{12} content of 0·25 mμgm., or less, per ml., on assay with *Euglena gracilis*[8].

Hog intrinsic-factor concentrate (supplied by Ayerst, McKenna and Harrison, Ltd., Montreal) was optimally active in the Schilling test in a dosage of 100 mgm. per 0·5 μgm. vitamin B_{12}. Normal human gastric juice was obtained, after histamine stimulation, from at least six donors. The juice was filtered

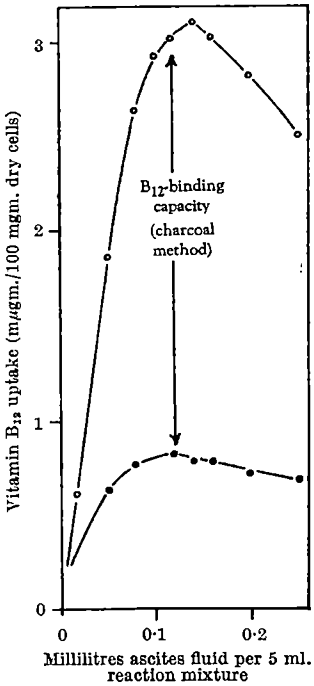

Fig. 1. Uptake of cobalt-58 vitamin B_{12} by Ehrlich ascites tumour cells with varying concentrations of ascites fluid. Vitamin B_{12}-binding capacity of ascites fluid by charcoal adsorption method was 5 mμgm. B_{12}/0·12 ml. ascites fluid. (5 ml. incubation medium contained 5 mμgm. cobalt-58 vitamin B_{12} and approximately 10 mgm. dry weight of cells.) ○—○, Uptake in 60 min. ●—●, uptake in less than 1 min.

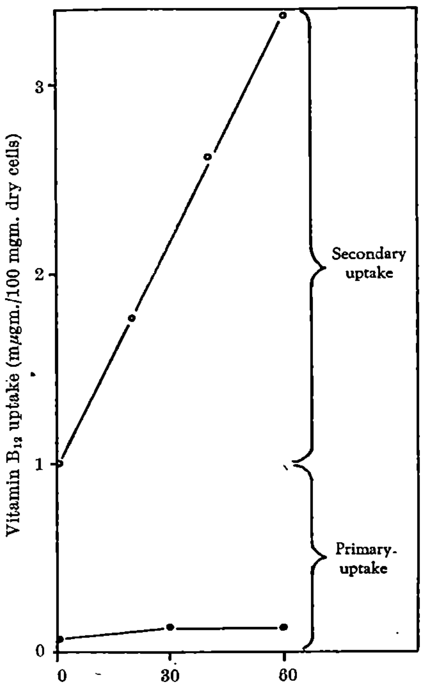

Fig. 2. Rate of uptake of cobalt-58 vitamin B_{12} by Ehrlich ascites tumour cells. (5 ml. incubation medium contained approximately 10 mgm. dry weight of cells.) ○—○, Medium contained 5 mμgm. cobalt-58 vitamin B_{12} and 0·12 ml. ascites fluid per 5 ml.; ●—●, medium contained 5 mμgm. cobalt-58 vitamin B_{12} per 5 ml., but no ascites fluid

through cheesecloth, adjusted to *p*H 10 to destroy pepsin, and neutralized to *p*H 7·0. The human serum, gastric juice, and mouse ascites fluid were stored separately in small aliquots at −20° C. until they were used.

The tumour cells were incubated in flasks containing 2–5 mμgm. cobalt-58 vitamin B_{12} (obtained from Merck of Canada), together with human serum or appropriate quantities of other B_{12}-binding materials, in the presence of Krebs–Ringer phosphate solution. Flasks were incubated at 37° C. in an atmosphere of air in a constant-temperature shaking water-bath. After an appropriate incubation period, the cells were removed by centrifugation and washed three times in cold phosphate-buffered saline. The cells were then resuspended in 1 ml. of water and counted in a well-type scintillation counter.

Ascites cells were incubated with a constant quantity of cobalt-58 vitamin B_{12} and varying amounts of ascites fluid and the amount of vitamin B_{12} taken up by the cells was estimated. The augmentation by ascites fluid of vitamin-B_{12} uptake by the cells was found to be optimal when the B_{12}-binding capacity of the ascites fluid added was equivalent to the quantity of vitamin B_{12} in the medium (Fig. 1). The B_{12}-binding capacity of ascites fluid, as determined by a modification of the charcoal adsorption method of Miller[9], was found to be 41·6 mμgm. vitamin B_{12} per ml. A similar relationship was observed between the charcoal-binding capacity of human serum and the uptake of cobalt-58 vitamin B_{12} by HeLa cells.

The pattern of uptake by ascites cells of bound cobalt-58 vitamin B_{12} is shown in Fig. 2. Negligible uptake values were obtained when ascites cells were incubated in the absence of ascites fluid. However, the addition of ascites fluid to the reaction mixture resulted in a very rapid initial uptake, occurring within the first minute of incubation, followed by a slower uptake directly proportional to time for at least 60 min. Further experiments showed that the initial or 'primary' uptake was almost completely unaffected by changes in temperature or *p*H, whereas the slower, 'secondary' uptake was dependent on temperature and had a *p*H optimum at 7·4.

The effect of increasing concentrations of the ascites fluid–B_{12} on these two phases of uptake is shown in Fig. 3. Both describe exponential curves with increasing concentration. Similar observations were made with HeLa cells incubated in human serum.

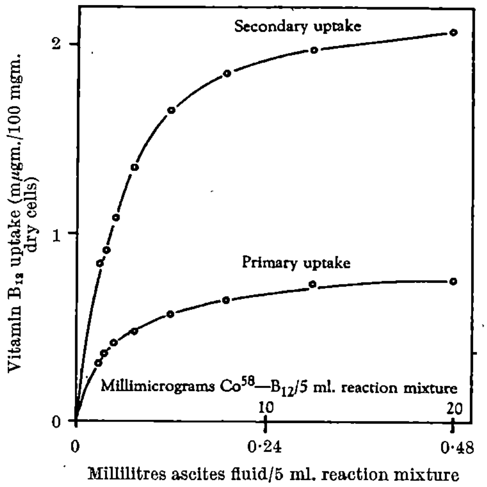

Fig. 3. Effect of varying concentrations of cobalt-58 vitamin B_{12} and ascites fluid on B_{12} uptake by Ehrlich ascites tumour cells. (5 ml. incubation medium contained approximately 10 mgm. dry weight of cells)

Both ascites cells and HeLa cells were found to take up the vitamin B_{12} only in the presence of certain fluids. HeLa cells took up vitamin B_{12} bound only to human serum, whereas vitamin-B_{12} uptake by ascites cells was stimulated by human serum, mouse ascites fluid, and mouse serum. Neither type of cell took up vitamin B_{12} bound to hog intrinsic-factor concentrate, human gastric juice, chick serum or calf serum. However, incubation with hog intrinsic-factor concentrate followed by incubation with cobalt-58 vitamin B_{12}, as described by Herbert[3], was effective in enhancing uptake by these cells: conversely, incubation with human serum or mouse ascites fluid followed by that of cobalt-58 vitamin B_{12} was not effective. This suggests that the phenomenon described here probably differs from that observed with rat liver slices by Miller[2] and Herbert[3].

In summary, mouse ascites fluid and human serum have been found to produce approximately a twenty-fold increase of uptake of vitamin B_{12} by mouse ascites tumour cells and by HeLa cells. Under the same conditions, human gastric juice and hog intrinsic-factor concentrate were ineffective in promoting uptake of vitamin B_{12}. Uptake of vitamin B_{12} occurring in the presence of mouse ascites fluid or human serum was found to be a bi-phasic reaction consisting of a rapid or 'primary' uptake which is probably of a physico-chemical nature, and a slower or 'secondary' uptake differing from the first in depending on temperature and possessing a *p*H optimum at 7·4.

We thank Dr. L. Lowenstein and Prof. J. H. Quastel for valuable suggestions and advice. Outflux of Inorganic and Organic Phosphate during Membrane Depolarization of Excitable Tissues

It was reported in a previous paper[1] that the outflux of phosphorus-32 from an isolated sartorius muscle of the frog into phosphate-free Ringer solution was accelerated markedly during electrical stimulation, or when the external solution was devoid of calcium or contained a high potassium (30 m*M*) concentration. Subsequent findings revealed that not only inorganic phosphate but also many organophosphates such as adenosine triphosphate (ATP) and phosphocreatine were released during membrane depolarization under such experimental conditions. The present communication concerns the outflux of nucleotides and other phosphates from frog sartorius muscle and spinal nerve roots during electrical stimulation and calcium depletion.

Isolated frog sartorius muscle was immersed in frog Ringer solution containing phosphorus-32 (carrier-free orthophosphate, 25 µc./ml.) for 2 hr. at room temperature (25° C.). In general, five paired muscles were used for each control and experimental run. The muscles were then washed in Ringer solution for 20 sec. and the initial soaking procedure continued for 2 hr., during which time the muscles were transferred every 20 min. into a series of beakers containing 10 ml. of phosphate-free Ringer solution. The extracellular phosphorus-32 was virtually washed out by this procedure[1]. The control muscles were then placed in 2 ml. Ringer solution (112 m*M* sodium chloride; 2 m*M* potassium chloride; 1·8 m*M* calcium chloride; and 2 m*M* sodium bicarbonate) and the experimental muscles in calcium-free Ringer solution (112 m*M* sodium chloride; 2 m*M* potassium chloride; 2 m*M* sodium bicarbonate; and 4 m*M* ethylenediamine tetraacetic acid (EDTA)) for a period of 1 hr. For stimulation experiments, the test muscles were immersed in Ringer for 40 min. while supramaximal electrical stimulation (1/3 sec. pulses) was applied through a pair of platinum electrodes dipped in Ringer solution. The final external solution was then run through a 'Dowex 1' anion-exchange column, and the phosphates separated and analysed as described elsewhere[2].

Two pairs of sciatic-spinal root nerve preparations were isolated from a bull-frog, and unilateral pairs used for test and control preparations. The nerve roots (ventral and dorsal) of the preparation were soaked in Ringer solution containing 50 µc./ml. of orthophosphate-^{32}P for 2 hr. (the sciatic nerves and spinal ganglia were kept exposed in a moist chamber during the whole course of the experiment). The nerves were washed and treated in the same manner described for the muscle preparations. The application of stimulation (50 pulses/sec.) and recording of action potential was carried out on the sciatic nerve for 40 min. The incubation medium was then analysed as in the case of muscle. The external solution contained phosphorus-32 originating from within the nerve fibre, while the phosphorus-32 of the interfibre was considered to diffuse out completely during the 2-hr. washing procedure (unpublished work).

Both the total amount and the specific activity of the tissue phosphates were studied in the external solution following incubation. In a calcium-free solution containing EDTA there was a considerable increase in all the phosphates examined, including

cytidylic and uridylic acid, the increase being greatest in inorganic phosphate and phosphocreatine. A small increase in the specific activity of phosphocreatine and ATP was observed, the activity in the other nucleotides being too low to compare. In the case of the electrically stimulated muscle, a 500 per cent increase occurred in inorganic phosphate, a 100 per cent increase in phosphocreatine, and 150 per cent in ATP. The other nucleotides, though showing a slight increase after stimulation, were present in only trace amounts. When frog spinal nerves were exposed to calcium-free EDTA solutions, a 200 per cent increase was noted in the concentration of inorganic phosphate, phosphocreatine and ATP, while the change in the specific activity of these fractions was insignificant. After electrical stimulation of frog nerves, a 50 per cent increase in the phosphorylated intermediates was observed.

The present results can be interpreted in a number of ways. The most likely interpretation is that there is a loss of calcium in excitable tissues exposed to either calcium-free EDTA solutions or electrical stimulation[3] This loss of calcium may result in a structural re-arrangement of the excitable membrane in such a way as to permit the loss of certain substances, either from the membrane itself or from the internal body of the tissue. The phosphates such as ATP may actually be intimately involved in the structural configuration of the membrane ; and with the breakdown or loss of ATP there is a concomitant change in membrane permeability, as well as membrane depolarization. It is conceivable that the calcium diffuses out of the tissue as a phosphate complex, since, at the *p*H of the cell, calcium would be expected to form a complex readily with such phosphates as orthophosphate and ATP. The loss of phosphocreatine, however, would tend to indicate that some of the phosphates, at least, are not associated with calcium. To some extent, the efflux of phosphates from muscle may be due to the contractile events, but, in view of the results with nerve roots, it appears that to a considerable extent the efflux is associated with membrane depolarization. It has been suggested elsewhere[4] that the high-energy phosphates in excitable tissues may be compartmentalized, and that the important phosphates, so far as excitation is concerned, may be associated with the membrane itself. Preliminary work indicates that the specific activity of the phosphates in the external solution obtained during incubation is greater than that in internal muscle or nerve. It is possible, therefore, that the phosphates leaking out during loss of calcium are probably those primarily associated with the membrane, and that they may be more intimately related to the chemical events associated with excitatory phenomena.

A Hydrostatic Function of the Accessory Respiratory Organs in Air-breathing Fishes

ACCESSORY respiratory organs in fishes have generally been thought to be concerned with breathing atmospheric air[1]. That, like any other gas-filled space, they can also be connected with the perception of hydrostatic pressure has not been reported earlier. In fishes, perhaps the very existence of a swim-bladder, which takes the major role in regulating the density of the fish[2] and functioning as a hydrostatic organ[3], has diverted attention from other gas-filled organs which may have a similar function.

The accessory respiratory organs are supposed to have developed in response to exceptional environmental conditions which made aquatic respiration inefficient[4]. They may be simple secondary pharyngeal folds as in *Ophicephalus*, or sets of complicated and highly evolved opercular branchial chambers as in *Clarias*, *Heteropneustes* and *Trichogaster*[5]. In every case, fishes possessing these organs are known to visit the surface to gulp air[6].

When such air-breathing fishes are subjected to variations in hydrostatic pressure, control of the volume of air contained in the accessory respiratory organs occurs. At increased pressure the air in the accessory respiratory organ is retained, the fishes stay at or near the bottom and postpone their visit to the surface for relatively longer periods. When the pressure is decreased, the fishes begin to float up until they release gas from their accessory respiratory organs. Even in bottom-living fishes such as *Clarias* and *Heteropneustes*, a small reduction in pressure of 6–7 cm. mercury causes gas bubbles to be released. Further reduction brings about more release of gas, and when the pressure is reduced by 60–65 cm. mercury, practically all the gas from the accessory respiratory organs escapes. At such a reduced pressure, fishes like *Ophicephalus* and *Trichogaster*, which have a functional, physolistic type of swim-bladder[7], float helplessly upwards after the gas from the accessory respiratory organs has been expelled. Other fishes such as *Clarias* and *Heteropneustes*, which have a non-functional physostomatous type of swim-bladder[8], when put under reduced pressure, make dashing movements to the surface to gulp air, but being unable to retain it, eventually sink to the bottom. To ensure that in these physostome fishes the release of gas occurs from the accessory respiratory organs and not from the swim-bladder, further tests were made in *Heteropneustes* by puncturing its accessory respiratory organs. As the accessory respiratory organs in this fish are long, paired, sac-like structures situated dorsally, the puncturing operation could be made without causing undue injury to the fish. When such fishes were subjected to a reduction in pressure, the air was partly expelled through the punctured opening and partly from under the operculum.

The above experiments clearly show that there are striking similarities between the accessory respiratory organs and the physostomatous swim-bladder. In both cases the fish can control the volume of gas by swallowing and releasing air, and in this way either of them can act as a hydrostatic organ. It is interesting to note that physostome fishes predominate in fresh-waters[9] and so do the air-breathing fishes. In some forms such as *Clarias* and *Heteropneustes* the swim-bladder has become reduced and non-functional. These fishes possess large and highly developed accessory respiratory organs presumably to compensate for the hydrostatic function of the swim-bladder as well as acting as respiratory organs. Such a correlation does not seem merely an accident, for in many fishes the swim-bladder acts as a respiratory organ[3]. It is therefore less surprising to find the accessory respiratory organ taking a part in the hydrostatic function.

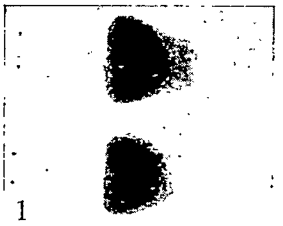
HÆMATOLOGY

Abnormal Fœtal Hæmoglobins

During the past few years, certain human fœtal hæmoglobin (Hb) variants characterized by electrophoretic mobility different from that of fœtal hæmoglobin have been described. They are: the Hb of Fessas and Papaspyrou[1], characterized by mobility at alkaline *p*H, faster than that of Hb *F*; Hb Bart's described by Ager and Lehmann[2], and also characterized by mobility at alkaline *p*H faster than that of Hb *F*; Hb Alexandra, slower than Hb *F*, described at the same time by Fessas *et al.*[3] and by Vella *et al.*[4].

The two fast hæmoglobins (Hb of Fessas and Papaspyrou and Hb Bart's) are most probably the same hæmoglobins. In fact, both these hæmoglobins have electrophoretic mobilities at alkaline *p*H between those of Hb *J* and Hb *H* (refs. 2–5) and at acid *p*H anodic mobility slightly lower than that of Hb *H*; their resistance to alkali denaturation is greater than that of Hb *A* but smaller than that of Hb *F* (refs. 2–5); their ultra-violet spectra are of the fœtal type (refs. 2–5), and in chromatography at *p*H 6 they have greater mobility than Hb *H* and any other type of hæmoglobin[2–5,6].

Hb Alexandra has been found rather frequently[6] in new-born Asiatic infants (Chinese, Malayans, etc.). Its mobility at alkaline *p*H is between that of Hb *S* and that of Hb *E* or A_2; it does not separate from Hb *F* on agar-gel electrophoresis at acid *p*H or on ion-exchange chromatography; its resistance to alkali denaturation and its ultra-violet spectrum are similar to those of Hb *F*; it gradually disappears during the first post-natal months.



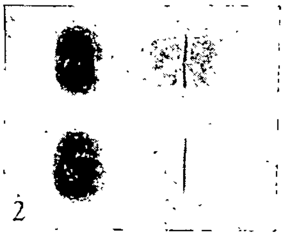


Fig. 1. Paper electrophoresis of Hb Bart's (399 *F*, above) and cord blood control (below). Glycine buffer *p*H 8·8, ionic strength 0·04. Staining with bromophenol blue. Greater mobility of fast fraction than of cord blood hæmoglobin

Fig. 2. Starch gel electrophoresis of Hb *H* (above) and Hb Bart's (390 *F*, below). Phosphate buffer *p*H 6, ionic strength 0·12. Staining with amido-Schwarz. Identical mobility of faster fœtal fraction and Hb H_2 fraction

In a survey conducted among the Italian population on 1,200 samples of the umbilical cord blood of new-born infants, we have found two cases which had a fast fraction and one with a slow fraction.

The fast hæmoglobin has greater electrophoretic mobility at alkaline *p*H than that of the mixture of Hb *A* + Hb *F* (Fig. 1) and is very similar to that of fraction H_2 (the less fast of the two fractions present in carriers of Hb *H*, ref. 7). At acid *p*H, its anodic mobility is identical with that of fraction H_2 of Hb *H* carriers (Fig. 2).

Agar-gel electrophoresis at acid *p*H reveals between fraction *F* and fraction *A* two very small spots near each other which are, however, also found in umbilical cord hæmoglobins without a fast fraction, and which correspond probably to the two small fractions which normally precede Hb *A*.

On 'Amberlite *IRC*-50' column chromatography at *p*H 6, the fast fraction does not appear to be identifiable, probably due to the small quantity present.

Quantitatively (Table 1) the amount of fast Hb is small. The ultra-violet absorption spectrum of the isolated fast fraction is identical with that of Hb *F*; the alkali-resistance of the isolated fast fraction[8] is 4–5 min., which is intermediate between the resistance of Hb *A* and that of Hb *F*.

It is evident that the fast hæmoglobin has all the characteristics of Hb Bart's or Hb of Fessas and Papaspyrou. These characteristics are, however, identical also with those we found for H_2. In a previous survey[7] on 5 cases of Hb *H*-microcythæmia, we have shown the constant presence of two fractions of Hb *H*, one faster, Hb H_1, and one less fast, Hb H_2; and we have shown that Hb H_2 has a fœtal type of ultra-violet spectrum, whereas Hb H_1 has a normal

Borate buffer *p*H 8·4, ionic strength 0·06. Staining with amido-schwarz. The slow fœtal fraction is faster than Hb A_2

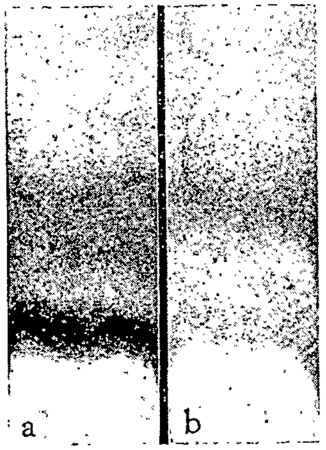

Fig. 4. Chromatography on columns of 'Amberlite *IRC*–50' of cord blood hæmoglobin with (*a*) slow fraction (0153 *F*) and (*b*) normal cord blood hæmoglobin. Citrate buffer *p*H 6, ionic strength 0·05. The slow fœtal hæmoglobin lies between *A* and *F* bands

spectrum. This finding has also been reported in the literature[9].

Hb Bart's and Hb H_2 have therefore the same electrophoretic and spectrophotometric behaviour (Table 1). It is now known[10] that Hb Bart's is a hæmoglobin composed of γ-chains only, that is, a fœtal hæmoglobin without α-chains, and Hb *H* (chromatographically separated)[11] consists of β-chains only, that is, it is an adult hæmoglobin without α-chains. It can therefore be deduced that Hb H_2 also consists of γ-chains only and Hb H_1 (corresponding to Hb *H* of the literature) of β-chains only: this would agree also with the spectrophotometric properties of these fractions.

The Hb of Fessas and Papaspyrou[1] and Hb Bart's[2] were originally described in microcythæmic new-born infants and later found to be present even after infancy; Tuchinda *et al.*[9b] and Boyo *et al.*[12], on the contrary, have reported disappearance of the fast fraction within three months after birth.

In the present two cases, an examination after three months showed that the fast fraction had disappeared. No trace of microcythæmia has been found in the children or their parents. The conclusion must be drawn that Hb Bart's, present at birth in non-microcythæmic individuals, disappears within a few months, whereas Hb Bart's, which appears in carriers of microcythæmic syndromes, persists.

The slow fœtal hæmoglobin, identified in one case during the survey, has a mobility at alkaline *p*H higher than that of Hb A_2 (Fig. 3) and lower than that of Hb *S*. On acid *p*H paper, starch-gel or agar-gel electrophoresis, it does not separate from Hb *F*. Chromatography reveals, in our hands, in tests extending over more than 36 hr., the separation of an intermediate band between that of Hb *F* and that of Hb *A* (Fig. 4) which does not appear in fœtal hæmoglobins without the slow fraction. This differs from the finding described in the literature for Hb Alexandra and requires confirmation.

A small amount of this slow hæmoglobin is also present (Table 1); it is always greater than the amount of fast fœtal Hb. The ultra-violet spectrum of the slow fraction isolated is of the fœtal type, but the alkali-resistance test also gives results for this hæmoglobin intermediate which are between those of Hb *F* and those of Hb *A*.

This investigation has been supported by a grant from the National Council of Research.

Thalassæmia and the Abnormal Human Hæmoglobins

The preponderance of hæmoglobin *A* over hæmoglobin *S* in sickle-cell trait was observed in the course of our initial studies on the hæmoglobin of sickling cells[1]. Later work carried out in collaboration with other laboratories showed that the ratio of these hæmoglobins is inherited[2] and that simultaneous presence of a gene for an abnormal hæmoglobin and a gene for thalassæmia results in partial or complete suppression of synthesis[3,4] of hæmoglobin *A*. An exceptional case in which presence of a thalassæmia gene did not alter the proportion of hæmoglobins *A* and *C* in hæmoglobin *C* trait was observed elsewhere[5]. These findings formed the basic evidence on which we proposed the following concepts about the inheritance of hæmoglobin: (1) alleles may be present that control the synthesis of hæmoglobin *A* at different rates[6]; (2) there may exist more than one locus for thalassæmia[7]; (3) in some cases thalassæmia and abnormal hæmoglobins may be controlled at the same locus[8]; (4) a structurally abnormal but electrophoretically normal hæmoglobin may be synthesized at sub-normal rate in thalassæmia[8,9].

The discovery[10] of a chemical abnormality in hæmoglobin *S* and the discovery[11] of two types of polypeptide chains in hæmoglobin *A* resulted in further additions to the theory of inheritance of hæmoglobin, namely, that control of the structure of hæmoglobin and control of its rate of synthesis are properties of the same allele, and that separate genetic control of synthesis of the two chains would result in four hæmoglobins in double heterozygotes; these postulates about the inheritance of thalassæmia and the abnormal hæmoglobins were given in a review[9] in 1957. The concepts that the alleles controlling the synthesis of myoglobin, adult hæmoglobin, fœtal hæmoglobin and hæmoglobin A_2 evolved from the same primitive allele and that comparative structural studies might reveal similarities in amino-acid sequence or position were proposed in the same review[9]. The presence of four hæmoglobins in double heterozygotes and the existence of structural analogies between hæmoglobin and myoglobin have been corroborated recently[12–16].

That chemical studies reported since 1957 have not substantially altered our inferences is evident from the conclusions expressed by Ingram and his associates in a recent series of papers[17–20]. These papers are remarkable for the extent to which the custom of giving pertinent references to the ideas and findings of others has been ignored.

An experimental test of our thalassæmia hypothesis by comparison with the amino-acid composition of peptides of hæmoglobin from normal human beings and patients with thalassæmia major was proposed by Ingram and Stretton[17]. We point out that thalassæmia minor, in which, according to our hypothesis, a mixture of normal adult and thalassæmia hæmoglobins is present, is a more readily available source of hæmoglobin than thalassæmia major, and might be used for this purpose. The observation of non-integral numbers of two amino-acid residues per molecule of hæmoglobin from a subject with thalassæmia minor would indicate the presence of an inherited variant with a single amino-acid substitution in the hæmoglobin of thalassæmia. The fractional deviation from the proper ratio of integral numbers would be proportional to the relative rates of synthesis of hæmoglobin *A* and thalassæmia hæmoglobin.

Familial differences in the ratio of hæmoglobin *A* to hæmoglobin *S* in sickle-cell trait were ascribed by one of us[9] to different alleles that result in electrophoretically indistinguishable but chemically distinct forms of hæmoglobin *A*. Accurate chemical analyses of the hæmoglobin *A* of sickle-cell-trait subjects with different inherited ratios would provide a test of this hypothesis. Furthermore, non-integral numbers of two amino-acid residues in the hæmoglobin of a normal individual would suggest heterozygosity in two inherited variants of hæmoglobin *A*.

Total amino-acid analyses of hæmoglobin or its constituent chains would fail to detect one type of alteration that has been suggested as a possible basis for electrophoretically identical subtypes, namely, the transposition of amino-acid residues in a chain[21]. Analysis of peptides obtained by tryptic digestion would also fail to detect transposition if the transposed segment did not contain a basic amino-acid. A search for such an alteration by complete sequential analyses of different samples of hæmoglobin *A* would be a formidable task for any laboratory. However, a number of laboratories are studying the amino-acid sequence of hæmoglobin *A*, with use of samples from different sources. If disagreements emerge with regard to the sequence of residues in polypeptide fragments of identical composition, inherited transpositions must be considered as a possible explanation.

PATHOLOGY

Anaphylactoid Reaction in Rats

THE primary injection of dextran or egg white into rats produces hyperæmia, pruritus, and œdema of the face, tongue and paws; symptoms of the so-called anaphylactoid reaction[1]. While studying factors which modify this reaction, it became apparent that a proportion of rats failed to show this response. This problem was therefore examined in detail.

Most of the experiments were performed on groups of either male or female albino Wistar rats obtained from the Agricultural Research Council's Field Station at Compton. Their diet consisted of cubes (No. 41, Associated London Flour Millers, Ltd.) and they were allowed drinking water *ad lib.* The initial dose of dextran was 0·3 ml. per 100 gm. body-weight (180 mgm./kgm.). Fifteen out of 60 adult rats (25 per cent) failed to show the anaphylactoid reaction when this dose of dextran was given intraperitoneally, and a similar proportion did not react when the dextran was given intravenously together with Evan's blue dye. The animals initially resistant to this dose of dextran were resistant to doses of 0·05, 0·2 and 0·8 ml. per 100 gm. when tested at weekly intervals. Similar results were obtained when fresh egg white (10 ml./kgm.) or a second brand of dextran was used. The rats which did not respond to dextran also failed to respond when subjected to stress (withdrawal of food for 24 hr.). They were not diabetic, and the weights of their adrenal glands were similar to those of control rats. There was no deficiency in the 5-hydroxytryptamine content of the skin of rats not responding to dextran, and dextran was ineffective in these rats even when pre-treated with 5-hydroxytryptophan. The intravenous toxicity of histamine was also unchanged.

Procedures which potentiate the anaphylactoid reaction in control rats were then tried in animals not responding to dextran. Pre-treatment of the rats with insulin (4 I.U./kgm.) or chlorpropamide (100 mgm./kgm.) failed to facilitate the response, and so did adrenalectomy when the animals were tested at 6, 13 and 20 days after the operation. In these experiments, up to 50 per cent of the control animals died after showing the anaphylactoid reaction. When insulin and the stress of food withdrawal were used in adrenalectomized rats, the resistant animals again failed to show the anaphylactoid reaction.

In this work, 832 rats have been used, and no fewer than 162 (about 19·5 per cent) have failed to respond to dextran or egg white. When, however, some of the experiments were repeated using Sprague Dawley and hooded Lister rats, the anaphylactoid reaction developed at a fast rate, and no failures were obtained. Further work is now in progress to determine the characteristics of the strain specificity with regard to dextran. The immunological aspects of the problem may be of paramount importance in the study of human allergies.

Treatment of Thrombocytopænic Hæmorrhage with Œstriol Succinate

THE therapeutic indications for œstriol have, until now, been limited to the treatment of superficial conditions of the cervix, vagina and vulva, and to the relief of menopausal symptoms. At the dosage-level effective in these cases, œstriol has no effect on the endometrium and does not, therefore, lead to irregularities in the menstrual cycle or to uterine hæmorrhage.

I have recently carried out an investigation into the hæmostatic properties of a pure intravenous preparation of œstriol succinate (kindly supplied by N.V. Organon, Oss, Holland) in hæmorrhages of varying pathogenesis. It became clear very early in our investigations that this substance has a rapid effect on all types of thrombocytopænic bleeding, its action being particularly marked in the acute toxic and allergic thrombocytopænias.

The substance was administered to patients of normal weight in intravenous doses of 10 mgm. and provided adequate protection from hæmorrhages for about 48 hr. None of the 100 patients so far treated in this way has shown side-effects.

My investigations into the mechanism of the normal clotting process have demonstrated that œstriol succinate acts on this mechanism in two distinct ways: (1), a direct action on the blood vessels, reducing their permeability; and (2), an effect closely similar to that of thrombocyte factor 3. The latter action can be irrefutably demonstrated using the thrombokinase-formation test. Details of my work on the clotting mechanism will be published elsewhere.

No significant increase in thrombocyte count was observed during the above treatment. The dangerous incidents which occur all too frequently in the course of thrombocytopænia can, nevertheless, be rapidly and economically controlled in this way until such time as a more normal thrombocyte count can be restored by other means. I have had frequent recourse to œstriol succinate in cases with symptomatic thrombocytopænia consequent on leukosis, panmyelopathy and overdosage of cytotoxic agents. In addition, hæmorrhages following overdosage with anticoagulants, as well as post-traumatic bleeding in patients on anticoagulant therapy, can be better controlled when œstriol succinate is administered than on vitamin K therapy alone. This effect must be attributed to the direct vascular action of the preparation. Œstriol succinate, in view of its high therapeutic efficiency and its very good tolerance, has proved to have a wide field of application in this hospital, and one must hope that it will become generally available in the near future.

Effect of Enzyme Injections on Mitosis in Regenerating Liver

THE addition of deoxyribonuclease to tissue-culture media affected mitosis in tissue cultures[1,2]. In mice bearing Ehrlich ascites tumours, injections of the enzyme decreased the incidence of mitoses in the tumour cells and increased the survival-time of the animals[3]. Similarly, injections of xanthine oxidase and ribonuclease affected the rate of tumour growth and the survival time[4–6].

In view of these facts, it has been thought of interest to study the effect of deoxyribonuclease (DNase), ribonuclease (RNase) and xanthine oxidase on a rapidly dividing normal tissue such as regenerating liver following partial hepatectomy. (Deoxyribonuclease and ribonuclease were purchased from Worthington Biochemical Corporation, Freehold, New Jersey. The xanthine oxidase was a gift from Prof. F. Bergel, Chester Beatty Research Institute, London.)

Wistar rats of average weight 218 gm. (194–242 gm.) were partially hepatectomized (66 per cent) according to the method of Higgins and Anderson[7] between 9.30 and 11.30 a.m. to eliminate the variations due to the periodicity of mitotic activity[8]. The hepatectomized rats were injected intraperitoneally with sodium chloride 0·85 per cent or solutions of albumin, DNase, RNase (5 mgm./ml.), or xanthine oxidase in sodium chloride 0·85 per cent. The original solution of xanthine oxidase prepared in phosphate buffer containing sodium salicylate and ethylenediamine tetraacetic acid as preservatives

Table 1. EFFECT OF ENZYME INJECTIONS ON MITOSIS IN REGENERATING RAT LIVER

* Controls were injected intraperitoneally with 1 ml. sodium chloride 0·85 per cent or albumin (5 mgm./ml.) immediately after the hepatectomy. Groups DNase, xanthine oxidase and RNase (*A*) were injected intraperitoneally with 1 ml. of enzyme (5 mgm./ml.) immediately after the hepatectomy. Groups DNase and xanthine oxidase (*B*) were injected intraperitoneally with 1 ml. of enzyme (5 mgm./ml.) at 6 and 24 hr. after the hepatectomy.

† Statistically significant at a level better than 99·9 per cent.

was dialysed against two litres of sodium chloride 0·85 per cent during seventy-two hours in the cold. After dialysis, the enzyme activity was determined by a standard method[9] and the activity corresponded to the destruction of 1·27 μmole of xanthine per min. per ml. of solution.

Forty-eight hours after hepatectomy, the rats were killed by decapitation and the excised liver fixed in neutral 10 per cent formaldehyde. Histological sections were prepared by the usual method and stained with eosin and hæmatoxylin.

The incidence of mitotic figures in liver parenchyma was determined by differential counts. A reticule delimiting a square field was placed in one of the oculars of a binocular microscope and this field was placed at random over the histological section. The nuclei present in the field were examined under immersion and differential counts were made of resting cells, prophases, metaphases, anaphases and telophases. When all the nuclei present in a field had been examined, the counts were carried out in similar fields taken at random until at least 6,000 nuclei were counted. The results were expressed as the number of mitotic figures per hundred cells.

Table 1 shows the results obtained for the incidence of mitosis and mitotic phases in regenerating liver following the injection of control or enzyme solutions. The proportions of the mitotic phases are also included. From the results, it would seem that the mitotic activity was not much affected by enzyme injections. The largest variation was observed in the group xanthine oxidase (*A*) injected with a single dose immediately after hepatectomy and was of the order of 30 per cent. The incidence of prophases, on the other hand, was much affected in rats injected with DNase or xanthine oxidase. Decreases from 1·8 to 1·0, 1·0, 0·7, and 1·1 respectively were observed. The incidences of metaphases, anaphases and telophases, however, varied only slightly. The important decrease in the incidence of prophases became masked in the values obtained for the incidence of mitosis because it represents only a fraction of the mitotic activity.

The decreases in the number of prophases were reflected by significant decreases in the proportions of prophases relative to the other phases of the mitotic cycle. Significant increases in the proportions of metaphases were consequently observed. The injection of RNase did not affect the number of the various mitotic phases or their proportions.

Table 2 shows the most important cytological abnormalities observed in the mitotic figures. The control rats showed a few pycnotic metaphases as well as a few metaphases with one or two lagging chromosomes. These abnormalities were very frequent in the animals treated with DNase. In these animals it was also frequently noticed that chromosomes were lagging to join the two sets at anaphase and chromosomal bridges were present. In the animals treated with xanthine oxidase, pycnotic metaphases as well as colchicine-like metaphases were frequently observed.

Table 2. CYTOLOGICAL ABNORMALITIES

	Control	DNase
Chromosomes lagging to reach the equatorial plate in metaphase	rare, one or two chromosomes lagging	very frequent, many chromosomes lagging
Pycnotic metaphase	rare,	frequent,
Chromosomes lagging to join the two sets in anaphase	nil	frequent
Bridges of chromosomes in anaphase	nil	present
	Control	Xanthine oxidase
Colchicine-like metaphase	nil	frequent

From the results described it would seem that the duration of prophase has been shortened by the injection of DNase and xanthine oxidase as indicated by the significant lowering of the incidence of prophases. The metaphase and anaphase seemed also to be affected to a certain extent as shown by the abnormalities noted.

We acknowledge the help of Dr. Roger Boothroyd, of McGill University, in the classification of the mitotic abnormalities. Dr. Roger Daoust has been most helpful by his advice on differential counts. The work has been supported by grants to Dr. A. Cantero, director of the Research Laboratories, from the National Cancer Institute of Canada.

BIOLOGY

Myopathy affecting the Rottnest Quokka (*Setonix brachyurus*) reversed by α-Tocopherol

THE quokka (*Setonix brachyurus*) is a small marsupial about the size of a fox terrier which inhabits Rottnest, an island lying in the Perth Basin ten miles from the coast of Western Australia. In recent years the species has been extensively studied by the Department of Zoology of the University of Western Australia, as the potential offered by the animal for ecological research is unique.

For several years in Perth and overseas, paralysis of the hind limbs has been observed in the quokka while in captivity. This disease has hitherto ended fatally despite various therapeutic measures including antibiotics and antihelminthics. It is characterized by weakness of the hind limbs which begins insidiously but progresses rapidly to complete paralysis. There is marked wasting of the muscles of the pelvic girdle and the disease invariably terminates in death in a few days to several weeks. At autopsy pallor and atrophy of the pelvic and femoral groups of muscles are found. On histological examination of affected muscles individual fibres are swollen, fragmented and show variability of cytoplasmic staining. Many fibres are without nuclei, and in others there is pycnosis. There are proliferations of sarcolemmal cells and infiltrations of variable cellularity of lymphocytes, plasma cells and polymorphs. Metazoan parasites are not found.

Early in 1960 representative slides of the muscle lesion were sent to Dr. Raymond Adams, Bullard professor of neuropathology, Harvard Medical School, for his opinion. He replied that the cause of the paralysis and of the lesions observed might well be due to deficiency of vitamin E in the diet. Dr. ten Seldam, professor of pathology, University of Western Australia, came to the same conclusion when investigating other similar material for Dr. S. Barker of the Zoology Department. Accordingly experiments were undertaken to test the effects of vitamin E administration to paralysed animals.

Ten quokkas which developed paralysis while in captivity were selected for trial treatment. These animals were from several groups which were maintained on a standard diet of high protein (17–21 per cent) 'sheep cubes' consisting of bran, pollard, oat meal, linseed meal, whale meal, molasses, urea and mineral salts. This diet was supplemented with bread and green vegetables including lucerne, lettuce, spinach and grasses growing in the vicinity. Nine of the treated animals were given the vitamin orally in doses ranging from 200 to 600 mgm. over several days. In all these animals there was rapid and complete clinical recovery in two to three weeks. Only one of the ten animals died. It was moribund at the beginning of the experiment and failed to respond to the vitamin given by injection.

Table 1

Date	Quokka	Urine (vol. 24 hr.)	Creatine (24 hr.)	Creatinine (24 hr.)
27.10.60	6	27 ml.	24 mgm.	0·010 gm.
28.10.60	7	48 ml.	27 mgm.	0·008 gm.
2.11.60	8	92 ml.	58 mgm.	0·011 gm.
13.1.61	6	48 ml.	15·8 mgm.	0·03 gm.
13.1.61	7	67 ml.	36·8 mgm.	0·057 gm.
13.1.61	8	96 ml.	24·0 mgm.	0·079 gm.

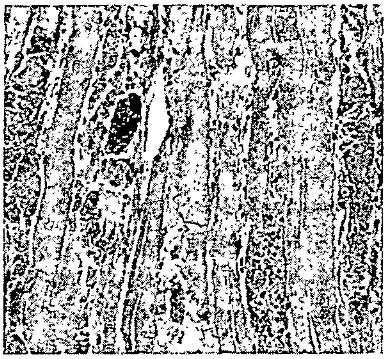

Fig. 1. Muscle biopsy of quokka 5. Original biopsy, October 17, 1960. Pronounced degenerative changes. (Hæmatoxylin and eosin × 78)

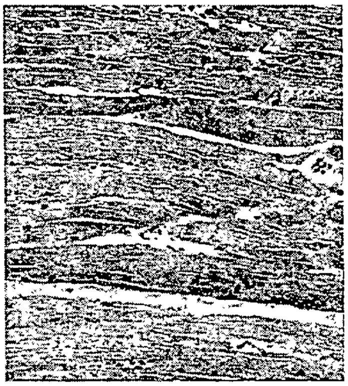

Fig. 2. Muscle biopsy of quokka 5. Second biopsy November 21, 1960. Restoration to normal. (Hæmatoxylin and eosin × 78)

Muscle biopsies were taken on the first or the second day of treatment. In the nine animals which recovered this first biopsy showed histological changes similar to those depicted in Fig. 1. In seven animals subsequent biopsy was performed at a site close to the original. These biopsies were taken from 1–8 weeks after clinical recovery. Two of the second biopsies showed the muscle to have completely recovered. In four others there was still minimal evidence of degeneration (Fig. 2), and in one no improvement of the lesion was observed notwithstanding the clinical recovery. In general, the longer the period was between biopsies the greater the observed improvement was in the histological appearances. 24-hr. samples of urine for creatine and creatinine estimations were taken from three of the animals at the time of the original biopsy and again after full recovery. The results, which support the clinical and biopsy findings, are given in Table 1.

Deprivation of vitamin E in the diet of the quokka is at present being tried in a small series of animals, and the early results suggest that the lesion can be induced in this manner. No control animals have died naturally or have shown evidence of disease.

Grateful acknowledgment is made to Prof. ten Seldam, who suggested this work, and for the advice and technical assistance given by Dr. I. Kaldor (Department of Physiology), and members of the Department of Zoology of the University of Western Australia. Mr. H. Upenieks, medical illustrator,

prepared the photomicrographs. The biochemical estimations were performed through the kindness of Dr. D. Curnow (Royal Perth Hospital). The α-tocopherol was kindly supplied by Roche Products, Ltd.

Structure and Action of the Sucker of *Echeneis*

FIG. 1 is a diagram of the sucker of *Echeneis* taken after staining it with alizarin red and rendering it transparent in glycerin. This reveals the presence of a chamber below the posterior shield of the sucker, about which no mention has so far been made in the literature. Hora[1], who at first doubted whether the sucker was a real sucker, later was convinced that the outer rim functioned as a sucker and that there were smaller paired suckers as well; Sewell's[3] observations confirmed this.

My observations show: (1) That in addition to the paired chambers there is an unpaired chamber below the posterior shield which has no opening on the dorsal side. (2) While all the other paired chambers are filled with sea water when the fish is swimming about, this chamber also contains some fluid but not sea water as there appears to be no connexion with the exterior. (3) At the posterior end of the chamber there is a pear-shaped hollow bony structure with one or more openings in it and there are two channels one on either side of it suggesting that by its movement forward and backward it can act as a valve regulating the flow of liquid in the chamber. (4) The entire base of the disk is paved with bone consisting of plates overlapping each other and with two pairs of holes in them. (5) The laminæ carry transverse bars against which the bases of the teeth abut, forming effective buttresses. (6) A pair of large hooks from the buttress interlock with the holes in the basal plates. (7) The pear-shaped, hollow, bony structure becomes completely detached when teased in caustic potash.

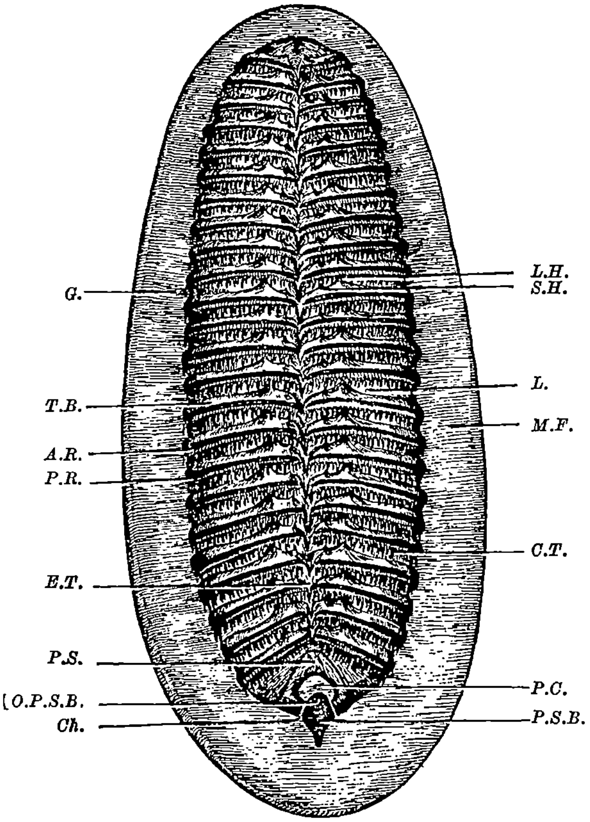

Fig. 1. The sucker of *Echeneis* as seen when stained in alizarin red and rendered transparent in glycerin. *A.R.*, anterior ridge; *Ch.*, channel; *C.T.*, comb-like teeth in three rows; *E.T.*, enlarged tooth pointing backwards; *G.*, glyph or spillway; *L.*, lamella between ridges; *L.H.*, large hook which fits into basal plate below; *M.F.*, marginal flap; *O.P.S.B.*, opening in pear-shaped body; *P.C.*, posterior chamber; *P.R.*, posterior ridge; *P.S.*, posterior shield; *P.S.B.*, pear-shaped body (valve); *S.H.*, small hook which fits into basal plate below; *T.B.*, transverse bar or buttress

The attachment presumably takes place in the following stages: (1) the marginal flap is the first to adhere; (2) the sea water is next sent out of the paired pouches from below the posterior ridge of each lamella; (3) next the interlocking of the lamellæ with the basal plates takes place; (4) any remaining water escapes by the spillways resembling siphonoglyphs; (5) the posterior shield is the last to adhere when the body fluid in the median chamber is withdrawn.

The release of the disk can be brought about by admitting sea water artificially: that is, by inserting sticks, strings or the blade of a penknife, but in Nature the processes mentioned above work in reverse. The posterior shield is the first to be released by the admission of body fluid into the chamber below it. Sea water now enters the space between the shield and the surface of adhesion and is carried to the siphonoglyphs, through which it enters, bringing about the release of the hooks. Water now is able to enter into the paired chambers, producing the "hissing sound" mentioned by Hora[2] and the "slight sucking noise" of Sewell[3]. During the process the water is strained free of all solid particles which might be floating in the sea water by the comb-like teeth. As each chamber is partly overlapped by the next a set of chain reactions occur so that all the paired pouches are progressively filled with sea water and the entire disk released.

Sewell mentions that when *Echeneis* is attached to any object all the movements of the fish except those of the mouth and gills seem to be suspended, and Norman[4], quoting it, says a detailed study of the nervous mechanism involved would be of interest. I venture to suggest that the movement of the body fluid in and out of the posterior chamber is obviously responsible for the setting of the nervous mechanism to work.

A detailed description of the sucker is in preparation, and it is expected to show that the sucker instead of being a partial vacuum is really a mechanism precisely built and as efficient as any that human ingenuity can invent, in which case the sucking power must be 15 lb./sq. in. As some of the suckers cover an area of more than 8 sq. in., the fish, theoretically at least, must be able to suck with a power exceeding 100 lb.

The Path of the Giant Cell Axons in *Aplysia depilans*

THE presence of large nerve cells in the abdominal ganglion of *Aplysia* has provided a valuable preparation for the study of the physiology of invertebrate neurones[1-8]. The largest cell is usually referred to as the giant nerve cell[1-3,6-8] and it may be 300–800μ in diameter. It is excited synaptically by pathways entering most, if not all, of the nerves of this ganglion, but its only efferent axon passes anteriorly along the right pleuro-visceral connective. As almost all the work on the abdominal ganglion has been done with it completely isolated from the rest of the nervous system, the further path of this axon and the possible functions of this very large cell have not been understood. Experiments, which included the insertion of micro-electrodes into this giant cell when the abdominal ganglion retained its functional connexions with the rest of the nervous system in a whole animal preparation, have provided evidence for the branching of this axon and have excluded certain possibilities concerning the function of the giant cell.

Fig. 1 summarizes diagrammatically the results of several different types of experiment which have confirmed one another. The axon of the giant cell after passing to the right pleural ganglion divides into branches which enter each of the main nerves innervating the right parapodium and the right side of the foot. Another branch continues forwards in the cerebro-pleural connective and through the cerebral ganglia to the left pleural ganglion. Exactly where the branching occurs is not certain; but, from the evidence available, that shown in the diagram seems the most probable. Electrical stimulation of any of the nerves containing a branch of this axon produces an impulse in each of the other branches. In these conditions, an antidromic spike is recorded in the giant cell following the passage of an impulse down the right pleuro-visceral connective. However, transmission between the different branches of this neurone is not always readily achieved, and repetitive stimulation is sometimes necessary. On the other hand, transmission often fails at relatively low frequencies. When this happens, however, it is not invariably preceded by a gradual lengthening of the delay which might be expected if a synaptic process were involved. Furthermore, delay between the application of the stimulus to one branch of the neurone and its appearance at another point is the same, regardless of the direction of impulse conduction. It may be assumed, therefore, that the failure of transmission in an antidromic direction is due to the low safety factor at the branching, especially as the more distant axonal branches are smaller than the main axon. A failure to conduct an impulse from the main axon to the branches in the orthodromic direction was never observed. Further confirmation was obtained by stimulating the giant cell itself by depolarizing the soma membrane and recording impulses with constant delays in the different nerves to which it sends a branch. In addition it is clear that, in spite of the axon crossing several ganglia, this cell is only excited synaptically in the abdominal ganglion. Different natural stimuli to an intact animal have never elicited a spike from a part of this neurone other than that contained in the abdominal ganglion.

Another giant cell has now been discovered on the left side of the animal. Work similar to that outlined above showed an almost identical pattern of branching (Fig. 1). The main difference is that in this case the cell body lies in the pleural ganglion and not in the abdominal ganglion. However, if the long axon in the right pleuro-visceral connective were shortened a symmetrical arrangement would result.

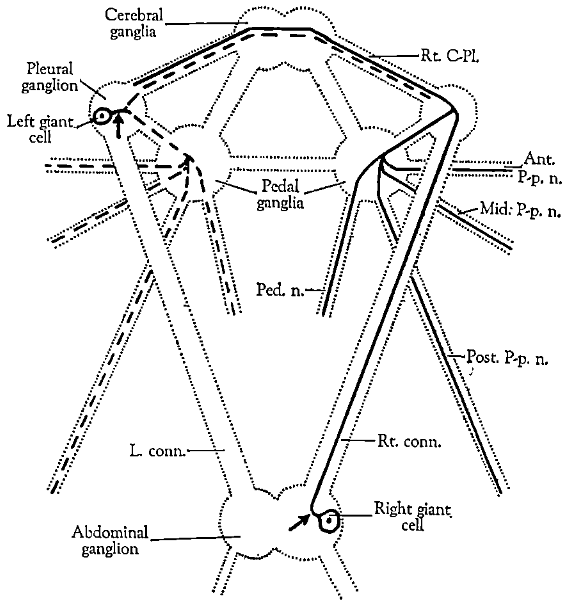

Fig. 1. Diagram of the path of the two giant cell axons in the nervous sytem of *Aplysia depilans*. Right cell, full lines; left cell, dashed lines. Arrows indicate the region where the giant neurones are excited synaptically. *Rt. C-Pl.*, right cerebro-pleural connective; *Rt. conn.*, right 'pleuro-visceral' connective; *Ant.*, *Mid.*, and *Post P-p. n.*, anterior, middle and posterior parapodial nerves; *Ped. n.*, pedal nerve

The precise homologies of the ganglia associated with the visceral loop in *Aplysia* are incompletely understood. This is mainly due to the absence of developmental evidence, and present views are based largely upon considerations of the external morphology of the central nervous system. The discovery that the largest cell on the two sides has basically the same distribution suggests the tempting hypothesis that they are homologous and that the cell bodies reside in different ganglia as a result of the complex morphogenetic changes which occur during torsion. In an idealized gastropod the visceral loop has along its length two parietal ganglia and a single or double visceral ganglion. If, following torsion, the right parietal ganglion became fused with the visceral ganglion, whereas the left ganglion or some part of it had remained fused with the left pleural ganglion, the difference in position of these two cells would be explained. Fusion of the right parietal ganglion (supra-intestinal) with the visceral ganglion is generally accepted, but the fate of the left parietal ganglion has not been established[9].

Little information has been obtained concerning the function of the left giant cell, because of the difficulty of recording from this cell in the intact preparation. Activity of the right giant cell has been recorded intracellularly in many preparations, and a study made of the conditions in which it becomes active. This occurs when mechanical stimulation is applied to any part of the body, with the head and gill region being the most sensitive. Excitation of the cell by either depolarizing currents passed through an intra-cellular micro-electrode or direct mechanical stimulation has not consistently evoked any overt movement of the animal. This disposes of the possibility that this cell is directly involved in the dorsal folding movements of the parapodia which occur when the animal is prodded and seem to represent a form of escape reaction. Nevertheless, during such movements of the parapodia which occur spontaneously in some preparations, the giant cell nearly always fires and it seems to be associated with this response although many other neurones in the abdominal ganglion do the same. It is clear that the giant cell does not have a function similar to the giant efferent neurones of other animals. Recordings were made from single neurones of the right pleural and pedal ganglia during stimulation of the giant cell and the abdominal ganglion. No evidence has been obtained for the existence of synaptic connexions between the giant cell axon and the cells which were sampled in several preparations. The possibility that this cell has an effect on the intensity or threshold of this defence response or other activities in the animal is difficult to investigate and remains a possible function of this very large cell.

This work was carried out in the Marine Biological Institute of Arcachon, France.

Maxillary Index in *Anopheles gambiae* Giles

Freshwater *Anopheles gambiae* may be distinguished as two co-existing biological races[1–3], on the basis of their maxillary indices, namely: (i) a paucidentate race, breeding in temporary pools of low organic content, which is anthropophilic and mainly exophilic, and (ii) a multidentate race, breeding in permanent types of water of high organic content, which is zoophilic and endophilic. Others[4–7] hold the opposite view, that the maxillary index is not a precise enough character for demonstrating this distinction. The present observations are in agreement with the reported breeding preferences of paucidentate and multidentate populations, but they also support the conclusion in ref. 6 that the larval environment has a powerful influence on the maxillary dentition.

Observations were made on three populations of *A. gambiae* (I, II and III), in the neighbourhood of Kampala, in Uganda, East Africa. Population I bred in a large temporary pond, on the Kampala-Hoima Road; II, in small, temporary, rain puddles, in an old road passing through Nakazi Swamp, on the Kampala-Bombo Road; and III, in permanent water, in the more exposed parts of Nakazi Swamp. Population I occurred some 10 miles from both II and III; while II and III were only 10–50 yards apart. The maxillary indices of the three populations are summarized in Table 1.

Table 1. Maxillary Indices (M.I.) of the Three Populations

Maxillary Index	Mosquito population and frequency (per cent)		
	I	II	III
9·5	2·5		
10·0	5·5		
10·5	12·5		
11·0	10·5	1·0	
11·5	27·5	3·0

12·5	17·0	13·0	1·5
13·0	3·5	19·0	4·5
13·5	6·0	24·0	11·5
14·0	0·5	15·0	17·0
14·5	1·0	13·5	25·0
15·0		5·0	9·5
15·5			11·5
16·0			6·0
16·5			8·5
17·0			2·0
17·5			1·0
No. mosquitoes dissected	200	200	200
Mean M.I.	11·64	13·38	14·66

Table 1 shows that population III had a higher maxillary index than either I or II; thereby supporting the conclusion reached by other workers[1–3] that multidentate populations tend to breed in permanent waters and the paucidentate in temporary waters. In this respect, the distinction between the maxillary dentition of II and III is particularly striking, in view of the close proximity of their breeding places. In such circumstances, genetic distinctiveness could not be maintained, unless there were sexual isolation between the two populations.

The difference in the maxillary dentition between populations I and II is also particularly interesting. The breeding water of I was less temporary, and, presumably, had a higher organic content, than that of II. It would, therefore, be expected that population I should have a higher maxillary index than II. The results (Table 1) show the reverse. The explanation of this anomaly may be found in the spatial relations of the three populations. If, as it has been suggested[1–3], we are dealing here with two co-existing biological races, the close proximity of the breeding places and, consequently, of the adult populations may have resulted in the production of a hybrid population (II) with an intermediate maxillary index. The distance between temporary and permanent breeding places may, therefore, affect significantly the difference between the maxillary indices of the respective mosquito populations.

That the maxillary index may be increased by increasing artificially the temperature of the breeding water is shown in Table 2. These results agree with those in ref. 6. However, the significance of these results, in relation to what happens in the field, is not obvious. The vast majority of *A. gambiae* breeding places are exposed, temporary, shallow pools, in which the water temperatures are often considerably much higher than in the less favourable, permanent-water habitats. Yet, the maxillary index is higher in the latter than in the former. It is probable that this discrepancy is due to the fact that the artificially high laboratory temperatures are made continuous; while those in the field occur for only a short period of the day and thus they fluctuate with the daily rhythm. In this respect, a study of the maxillary index of *A. gambiae* breeding in continuously high temperatures, in tepid water from hot springs[8], would be particularly worth while.

Table 2. MAXILLARY INDEX (M.I.) OF POPULATION I BRED IN FIELD WATER AT CONSTANT HIGH TEMPERATURE (32° C.) IN THE LABORATORY

Maxillary Index	Frequency (per cent)
13·5	1·7
14·0	12·1
14·5	20·7
15·0	15·5
15·5	20·7
16·0	12·1
16·5	8·6
17·0	5·2
17·5	1·7
18·0	0·0
18·5	1·7
No. mosquitoes dissected, 58; mean M.I., 15·31.	

Table 3 shows the results of laboratory experiments in which the organic content of field breeding-water was increased by adding fresh cow-dung to the water. It will be seen that the maxillary index of population I became higher. These results indicate that it is possible for an *A. gambiae* population which would otherwise have developed as paucidentate to change into a multidentate one, by the mere fortuitous dropping of dung by cattle into the breeding place. It has been postulated[9] that a higher maxillary index confers on the mosquito a greater ability to feed on cattle and other thick-skinned domestic animals. Consequently, it has been assumed that the prevalence of multidentate mosquitoes, in an area with a high cattle population, proves that natural selection has acted in favour of such mosquitoes. However, the present observations would seem to indicate that the co-existence of multidentate mosquitoes and high cattle populations, in an area, may simply be the result of a greater proportion of the breeding places being polluted with dung and other organic matter of animal origin; which, in turn, increases the maxillary dentition of the mosquitoes.

Table 3. MAXILLARY INDEX (M.I.) OF POPULATION I BRED IN 'COW-DUNGED' FIELD WATER IN THE LABORATORY (room temperature varied 22–25·5° C.)

Maxillary Index	Frequency (per cent)

Rectal Glands in Woodlice

THE structure and function of the rectal glands of insects have been investigated by several workers[1]. Later, Wigglesworth[2] studied these glands more thoroughly in a number of species. No report, however, has yet appeared in the literature regarding the presence of rectal glands in woodlice (Crustacea : Isopoda), although Edney[3] stated : "the fæcal pellets are moist, and there appears to be no mechanism comparable with the rectal glands of insects for reabsorption of water contained in the rectal contents". This observation, however, was not based on any experimental or histological studies.

The present report is concerned with two common species of woodlice in Great Britain, *Oniscus asellus* L. and *Porcellio scaber* Latr. Examination of the rectal contents of these animals shows that they are in a much more fluid state than the fæcal pellets, which are

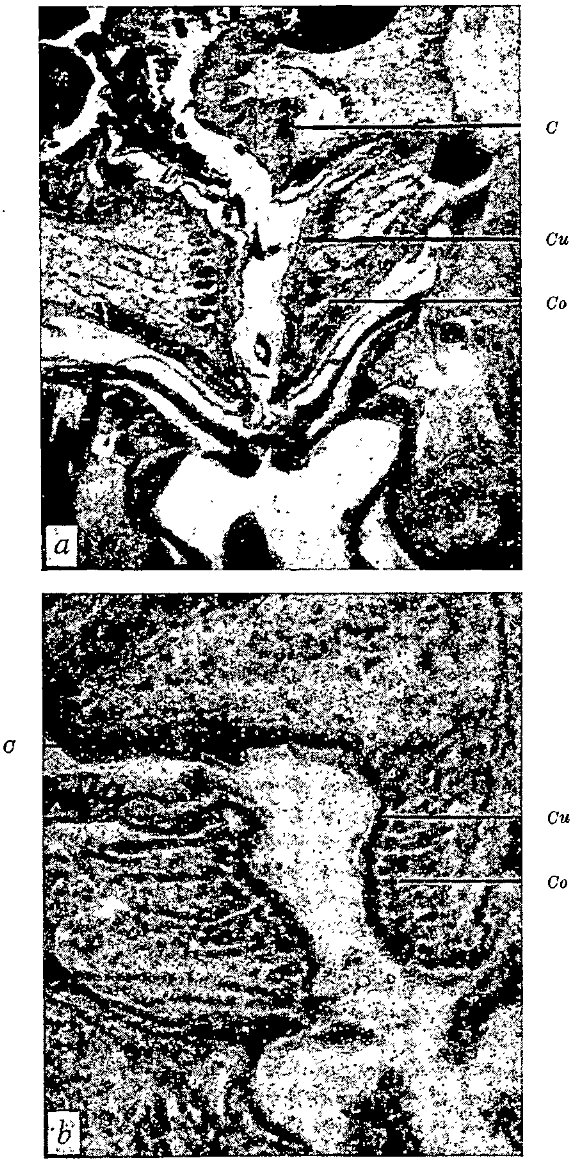

Fig. 1. Sections of the 'rectal gland' of (*a*) *Porcellio scaber* Latr.; (*b*) *Oniscus asellus* L. *C*, Cubical epithelial cell; *Co*, columnar epithelial cell; *Cu*, cuticle. (× 60)

finally discharged from the rectum in the form of rather black, large, solid, and cylindrical pellets. The water content of these pellets has been determined by Kuenen[4].

Considerable difficulty has been experienced by workers in the histological study of woodlice[5]. In the present work a variety of fixatives has been used[6], among which the best results were obtained with Carnoy's fixative. After fixing, the tissue was passed through decreasing strengths of alcohol down to water. In order to provide support, the tissue was embedded in agar and dehydrated. After double embedding, microtome sections were prepared in the usual way and the sections stained by the phloxine–tartrazine method of Lendrum[7].

In both *Oniscus asellus* and *Porcellio scaber* the lower part of the rectum is narrow, with a very thin cuticle covering cubical epithelium thrown into very small longitudinal folds (Fig. 1). In the posterior part of the rectum the cubical epithelial cells are absent and just below the cuticle lie columnar epithelial cells, tracheæ, muscle fibres and connective tissue. This structure is exactly similar to that described by Wigglesworth[2] in insects as rectal glands. These glands completely encircle the posterior part of the rectum.

Experimental evidence has been brought forward by Wigglesworth (ref. 2*a*) that rectal glands are concerned with absorption of water in insects. Water is the most important ecological factor in the habitat of woodlice, owing to the absence of cuticular wax layer. Desiccated woodlice are said to absorb water through the anus[8], and this has been confirmed in the present work. Further work is needed to elaborate the functions of the rectal glands in woodlice. Possibly these glands, too, are concerned with absorption of water from the rectal contents, although some is still lost in the fæcal pellets[4].

My thanks are due to Prof. J. L. Cloudsley-Thompson for his supervision during the work.

Mechanism of Differential Staining of Nucleic Acids

WORK in this Department, to be published elsewhere, has shown that several histological methods for the demonstration of mucin depend for their selectivity on the use of cations of large size. Thus alcian blue, with a molecular weight of about 1,341 (ref. 1), is almost specific for acid mucins, being apparently unable to enter other, more dense, basophilic structures. The dialysed iron method[2] similarly depends on the use of large particles (colloidal ferric hydroxide), while in Southgate's mucicarmine the small carmine molecule is probably adsorbed on to colloidal aluminium hydroxide.

Arising from this work, it was thought that size of cation might influence the selectivity of other commonly used basic dyes. In the present work, fourteen basic aniline dyes have been investigated, ranging in molecular weight from 264 to 1,341 (Table 1). A variety of formalin- or Helly-fixed tissues has been used, including frog pancreas, liver, ovary, intestine, stomach and kidney, rat trachea, stomach, pancreas and intestine, and monkey pancreas.

Table 1

Dye and source	Molecular weight	Cationic weight	Percentage solubility	
			Alcohol	Water
Alcian blue 8*GN*150 (I.C.I.)	*c.* 1,341	1,341 (?)	6·0	9·5
Victoria blue 4*R* (National Aniline Co.)	520	485	20·0	3·0
Janus green *B* (National Aniline Co.)	483	448	1·0	5·0
Bismarck brown *R* (National Aniline Co.)	461	388	3.0	1·5
Methyl green *OO* (Grübler)	458	387	3·0	8·0
Hofmann violet (Merck)	422	387	7·5	6·0
Crystal violet (National Aniline Co.)	408	373	8·75	9·0
Nile blue *A* (National Aniline Co.)	733	316	5·0	6·0
Safranin *T* (Merck)	351	316	3·5	4·5
Brillantcresylblau (Grübler)	318	282	2·0	3.0
Toluidine blue (Grübler)	306	271	1·75	3·25
Pyronin (Grübler)	302	267	0·5	9·0
Azur *A* (National Aniline Co.)	292	257	?	?
Thionin (Grübler)	264	229	1·0	1·0

(1) Molecular weights and solubilities in alcohol and water are from ref. 1. Cationic weights are calculated from data from the same source.
(2) One molecule of nile blue *A* gives rise to two cations on ionization.

In initial experiments 0·01 *M* aqueous solutions of the dyes were used, the stained, air-dried sections being mounted directly in '*D.P.X.*' (synthetic mountant, British Drug Houses). It was found that in these conditions sections were markedly overstained by certain dyes (notably victoria blue 4*R*, bismarck brown *R* and hofmann violet). It is noteworthy that most of the dyes concerned are more soluble in alcohol than in water (Table 1), and it is possible that this is a reflexion of some property common to this group of dyes, which is responsible for a loose, non-ionic bonding with tissue components. This is to some extent confirmed by the fact that thorough dehydration in ethyl alcohol (one minute each in 90 per cent, 95 per cent and absolute alcohol) was sufficient to remove the excess dye.

The results about to be described were obtained on sections stained for 15 min. in a 0·005 *N* solution of the dye in veronal-acetate buffer at *p*H 4·25, washed in tap water, dehydrated in alcohol and mounted in '*D.P.X.*'.

Under these conditions alcian blue (weight of cation about 1,341) stained nuclei minimally, and did not stain nucleoli or cytoplasmic ribonucleic acid. Victoria blue 4*R*, janus green, bismarck brown *R*, methyl green *OO*, hofmann violet and crystal violet (with cationic weights from 485 down to 373) stained nuclei more deeply than nucleoli or cytoplasmic ribonucleic acid, while safranin and nile blue (cationic weight 316) stained nuclei, nucleoli and cytoplasmic ribonucleic acid with approximately equal intensity.

Brilliant cresyl blue, toluidine blue, pyronin, azur *A* and thionin (cationic weights from 282 down to 229) stained nucleoli and cytoplasmic chromidial substance more intensely than they stained nuclei.

From these results it appears that dye cations having a combined atomic weight of between about 350 and 500 are able to penetrate into and become attached to nuclear deoxyribonucleic acid (DNA), but do not as readily stain the nucleoli and cytoplasmic granules of ribonucleic acid (RNA), which are presumably denser and better stained by smaller dye cations (of a combined atomic weight of less than about 280).

Differential staining of DNA and RNA by mixtures of two basic dyes (as in the classical methyl green/pyronin method) is now readily explicable. The proportions of the two dyes are chosen in such a way that the larger cation (methyl green) competes under favourable conditions for the DNA, while the smaller cation (pyronin) stains only RNA. If the principal factor in such differential staining is the weight of the dye cations, it should be possible to reproduce the 'methyl green/pyronin effect' (differential staining of DNA and RNA) with other pairs of basic dyes, provided that the dyes chosen are of sufficiently different cationic weights. The dyes must also, of course, be of contrasting colours, be mixed in appropriate proportions and be used at the correct *p*H.

To confirm this prediction, 1 per cent solutions of several basic dyes were prepared. Paraffin sections were stained for 15 min. in a mixture of a pair of such types (combined in various proportions), rinsed in tap water, dehydrated thoroughly in alcohol and mounted in '*D.P.X.*'. The following dye pairs stained DNA and RNA differentially under these conditions, when mixed in correct proportions: bismarck brown *R*/toluidine blue, bismarck brown *R*/azur *A*, victoria blue 4*R*/hofmann violet, victoria blue 4*R*/safranin, victoria blue 4*R*/pyronin, janus green/pyronin and janus green/safranin. In every case, the dye with the larger cation stained the nuclei, while the smaller cation stained nucleoli and cytoplasmic chromidial substance. A few nuclei, especially the small nuclei of frog red blood cells, stained with the smaller cation instead of the larger. This may be due to such nuclei lying wholly within the plane of the section; in such a case the nuclear membrane will be intact, and prevent access of the larger cation[3].

Dye pairs in which there was a large difference between the weights of the cations gave particularly good discrimination between DNA and RNA. Thus victoria blue 4*R*/pyronin or janus green/pyronin (mixed in a proportion of one part by weight of the larger cation to four parts of the smaller) gave results which compared favourably with those obtainable with the classical methyl green/pyronin method. Where the difference between the cationic weights of the two dyes was not large (for example, victoria blue 4*R*/hofmann violet), or where incorrect proportions of the two dyes were used, good differential staining of nuclei and nucleoli was sometimes obtained, but cytoplasmic RNA stained with both dyes. This is taken to indicate that the density of cytoplasmic RNA granules is intermediate between that of DNA and that of the nucleolus.

The use of basic dyes of varying cationic weights can also give some indication of the change in density of a structure under different conditions. Thus the staining of so-called 'depolymerized' DNA with pyronin instead of methyl green in the methyl green/pyronin method[4] probably indicates that the heat, or other treatment to which the DNA has been subjected, has altered its structure in such a way as to increase its density, and render access of the larger cation more difficult.

Dye-pairs in which there was relatively little difference between the cationic weights (for example, crystal violet/pyronin or safranin/thionin) gave little or no differential staining of DNA and RNA, irrespective of the proportions in which the dyes were mixed.

It appears from these results that the chemical explanations which have been advanced to explain the specificity of the methyl green/pyronin method[4] are unnecessary, the chief factor being the weights of the dye cations. The same factor explains the effect of the dye mixtures, malachite green/acridine red, methyl green/toluidine blue and celestine blue/pyronin, which give the same empirical results as methyl green/pyronin[4]; malachite green has a cationic weight of 328, celestine blue 329 and acridine red 240.

It should not be concluded from the above that the weight of the cation is the only relevant factor in staining with basic dyes. Mordants, *p*H, solubilities in various media, etc., may also play an important part in some procedures[5].

Dispersal of Tropical Seeds by Ocean Currents

DURING the winter of 1956 and the following summer, farmers living near the Ninety Mile Beach on the west coast of North Auckland (latitude 34–35° S.) noticed that numbers of unknown fruits and seeds, recognized as of tropical origin, were being washed ashore. Specimens were forwarded to the Botany Division, Department of Scientific and Industrial Research, by Mr. H. G. Halliwell, instructor in agriculture, Kaitaia, for identification.

The fruits and seeds were all of kinds known to be carried long distances by ocean currents[1]. They were: fruit of *Barringtonia asiatica*, fruits of a cycad, seeds of *Entada* sp. (nicker bean), *Guilandina crista* (Molucca bean or grey nicker), *Mucuna gigantea*, seeds apparently of two other species of *Mucuna*, and nuts of *Aleurites fordii* (candlenut). There was also a red leguminous seed 17 mm. long and an unidentified fruit, possibly from one of the Myristicaceae. Apparently nicker beans and candlenuts were the most common. According to a newspaper report[2], at times many coconuts were being washed up. Candlenuts from Mangonui, on the east coast at about the same latitude, were also sent in by Dr. A. Couper, of the Geological Survey. They were called in the north 'petrified walnuts'. Some of the material must have been afloat for a considerable time, for the *Barringtonia* fruit, most of the cycad fruits, and many of the nicker beans had remains of a polyzoan on them, and were sometimes quite covered.

Although the number and variety seem to be unusual, this is not the first time that tropical seeds have drifted to New Zealand. It was known in Auckland thirty or so years ago that nicker beans were cast up on the coasts of North Auckland from time to time. The newspaper report refers to present conditions as "a reversion to an earlier pattern of ocean currents" and says "in greater profusion than in past years all sorts of tropical flotsam are being cast up".

Seven out of twenty-two seeds of *Entada* sown at Lincoln, Christchurch, in November 1956, germinated about 21 months later. Two of the plants are now growing in the glasshouses, one a vine 4 ft. long, the other 8 ft. Another plant in the tropical house, Botanic Gardens, Christchurch, is 12 ft. long. In North Auckland plants have been grown successfully outdoors by local farmers, and one plant is reported to have grown to a great height. As *Entada* sp. in Fiji is most characteristically found in the mangrove formation and also grows in the forest[1], it seems unlikely that it will become established of its own accord on the Ninety Mile Beach, an exposed shore backed by sand-dune country.

The candlenuts were either empty or the seed had decayed into a soft oily mass, as reported previously for seeds of this species carried by ocean currents.

Classification of the Tea Plant

Dr. W. Wight, referring to Watt and Mann's categories of leaf-form within the Assam variety of tea plant[1], goes on to say: "Number of leaf veins was emphasized; but this has not proved to be a satisfactory criterion". I may say at once that Watt was solely responsible for the leaf vein idea for separating the varieties of tea. When I wrote, with him, the second edition of the *Pests and Blights of the Tea Plant* I had to include the leaf vein idea, but I never was, myself, able to make anything out of it. I never agreed with Watt on this subject, and it was included in our book in deference to him. Thus, so far as I am concerned, the number of leaf veins was an unsatisfactory criterion fifty-seven years ago.

Staining Reaction of the Pit Membrane of Wood Cells

In a recent paper Harada and Wardrop[1] report that the lignin content of the ray parenchyma cell walls of *Cryptomeria japonica* (Linnæus fil.) Don. is about 43·5 per cent and also that the lignin is distributed nearly uniformly through the cell walls. In view of the bearing on their observations and also the possible relation to the movement of materials through wood, the results of the reaction of the pit membrane when wood sections are treated with differential stains are recorded.

Radial longitudinal sections of approximately 10μ were stained with safranin and fast green according to the following schedule: (1) Sections warmed with aqueous safranin for 3–5 min.; (2) washed with several changes of water and then dehydrated in the normal way with ethyl alcohol; (3) stained with fast green in clove oil for approximately 15 sec. (this time can be increased with dilute fast green); (4) washed with clove oil, cleared with xylene and mounted in canada balsam. Washing was continued until the wash liquid was colourless.

In the following species the pit membranes of the ray parenchyma to tracheid pits were stained green in contrast to the red stained unpitted wall:

Pinus radiata D. Don, *P. khaysa* Royle, *Pseudotsuga menziesii* (Mirb.) Franco, *C. japonica*, *Callitris hugelii* (Carr) Franco, *Abies lasiocarpa* (Hooker) Nuttall. The pit membranes of the ray tracheid to tracheid pits were not differentiated to the same degree as the ray parenchyma pit membrane. Both in *P. radiata* and *C. hugelii* the torus of the bordered pits of the tracheids was stained green.

With the following species the membranes of the ray parenchyma to vessel pits and the parenchyma pits generally were differentiated green in contrast to the unpitted cell wall, which was stained red:

Sloanea woollsii F. Muell., *Elaeocarpus grandis* F. Muell., *Cryptocarya glaucescens* R. Br., *Flindersia schottiana* F. Muell., *Toona australis* Harms, *Sterculia acerifolia* A. Cunn., *Eucalyptus viminalis* Labill., *E. pilularis* Sm., *E. microcorys* F. Muell. Due to their small size the pit membranes of the fibres were hard to detect, but in a number of the above species a distinct green coloration was obtained. Of the species examined, only *Nothofagus moorei* J. H. Maiden failed to show differentiation of the pit membrane of the ray-vessel pits. The pit membrane in this species appeared to be masked by abundant polyphenolic materials.

Where possible, sapwood rather than heartwood was used for these observations as it was found that the polyphenolic materials deposited during the transition from sapwood to heartwood obscured the pit membrane, showing instead a red stain with the safranin.

According to Johansen[2], safranin and fast green adequately differentiate lignified and non-lignified tissue, so that this differentiation indicates that the pit membranes in a number of cells are not lignified. This observation is interesting, as it is those layers which make up the pit membrane, namely, the primary wall and middle lamella, which have the highest concentration of lignin in the unpitted cell wall[3]. The pit membrane, therefore, retains the unlignified condition of the newly differentiated cell wall and explains how the remarkable expansion of the pit membrane which occurs during tyloses is possible. The tylosed pit membrane in *Angophora costata* Domin. and *E. microcorys* on the basis of the above staining reaction did not appear to be lignified.

While Liese[4] and Harada *et al.*[5] describe encrusting material present in the pit membrane, it would appear that this material is not lignin. The absence of lignin in the pit membrane has been indicated by means of other techniques by A. B. Wardrop (private communication). The fact that lignin is confined to those parts of the wall where a secondary wall is formed implies very selective deposition, as mentioned by Wardrop and Bland[3]. The foregoing staining reaction serves also as an excellent technique for clearly defining the size and shape of the pit membrane and it has been suggested that this technique should have general application in anatomical work.

A Sealing Compound for use in Biological Work

In the course of rhizosphere studies, it was desired to measure continuously the respiration of intact sterile roots during the growth and development of a variety of plants. To separate the photosynthetic and respiratory activities of the portions above ground from the respiration of the roots, a material was required to prevent diffusion of gases from one zone to the other. The material had to fulfil several requirements in order to be effective : (1) be impermeable to gases and water ; (2) be non-toxic to plants ; (3) cause no physical damage to plants ; (4) be sufficiently pliable to permit normal enlargement of stems ; (5) withstand a continuous positive pressure of 0·5–1·0 lb./in.^{2}; (6) resist microbial and environmental deterioration; (7) be autoclavable; (8) be easily handled and applied; (9) be relatively inexpensive.

Although a variety of substances was tested, only one compound has been found which fulfilled all these requirements. This material is a viscous silicone fluid which solidifies at room temperatures on the addition of a catalyst. (Material is marketed by the Dow Corning Corporation, Midland, Michigan, under the trade name of 'Silastic *RTV*' (room temperature vulcanizing silicone rubber), and by the General Electric Co., Silicone Products Department, Waterford, New York, under the name of 'Silicone Rubber *RTV*'.) The time for complete vulcanization can be controlled by the type and amount of catalyst used ; working time can be adjusted from 10 min. to several days. The plasticity can be increased by the addition of a silicone thinner (Dow Corning '200 Fluid', 20 centistokes). The base, catalyst, and thinner may be autoclaved separately and mixed aseptically just prior to pouring around the stem.

The rubber-like solid forms an impermeable seal with glass, metal, certain plastics, sand, and with plant roots and stems. Although a continuous positive pressure of only 0·5–1·0 lb./in.^{2} is regularly used in our work, the material is capable of withstanding considerably higher pressures, both positive and negative. A layer 10 mm. thick and 38 mm. in diameter withstood a continuous positive pressure of 7 lb./in.^{2} and a continuous negative pressure of 500 mm. mercury; a layer 10 mm. thick and 70 mm. in diameter withstood a pressure of 2 lb./in.^{2}. At higher pressures, the sealer itself does not leak, but the interface bond between the sealer and either the wall of the glass tube or the plant stem is ruptured.

Although a gas-tight seal is formed around the stem of plants, the seal is sufficiently pliable to permit normal development of the stem as well as of the entire plant. The consistency of the vulcanized product does not change during autoclaving nor during prolonged use, and may be employed at temperatures ranging from -70 to 500° F. Other physical and chemical properties are described by the manufacturers.

In our work, surface sterilized seeds are planted in short glass growth tubes (38 mm. internal diameter) contained in specially designed culture units, which will be described fully elsewhere. The roots grow into a sterile respiration chamber, and the upper portions of the plant are allowed to develop in air. To separate the two zones, the sealer is poured around the plant stem inside the growth tubes and allowed to solidify before a continuous air-stream is passed through the root respiration chamber. Both monocotyledonous and dicotyledonous plants have been successfully cultured in the presence of this material : legumes and corn have produced fruit ; cotton, crucifers, cucurbits, and seeded bananas are at present growing vigorously.

Other compounds tested as sealers were not suitable for several reasons. Various combinations of paraffin, petrolatum and lanolin, as well as some carboxyvinyl polymers, were extruded from the growth tubes when pressure was applied ; this difficulty was accentuated when the temperature of the environment was high. Several materials, for example, latex, poly*iso*butylenes, urethane polymers, polyacrylic and polyvinyl resins, were toxic; some set too rapidly for easy handling ; some, for example, urethane polymers and some microcrystalline waxes, cured to a consistency that constricted the stem and prevented normal development ; some, for example, various paraffin-petrolatum mixtures, butyl-latex emulsions, distilled acetylated monoglycerides, carboxyvinyl polymers, shrank on curing and failed to form a gas-tight interface with either the glass tube or the plant stem ; some did not withstand autoclaving ; and others, such as the polyethylene glycols, being water-soluble, were dissolved by condensation, transpiration and guttation water.

In addition to being used in sterile root cultures, the silicone material is also being employed in these Laboratories to seal surface-sterilized intact roots in tubes containing root-infecting organisms (Halmos, S., and Beckman, C. H., unpublished results) ; to make gas-tight gaskets for attaching respiration and transpiration chambers to leaves[1] ; to make impressions of leaf surfaces for microscopic examination (Brun, W. A., unpublished results ; and Zelitch, I., unpublished results) ; and to make closures for odd-shaped and hard-to-reach openings which pre-manufactured rubber stoppers do not fit. Additional applications are described by the manufacturers.

The non-toxicity of this compound to plants, as well as its other properties, should make it useful in a variety of biological studies.

MICROBIOLOGY

Activation of Amino-Acids in Micro-Organisms which produce Antibiotics

It seems well established that the first steps in the biosynthesis of proteins are the activation of amino-acids in the presence of adenosine triphosphate (ATP) and the transfer of the activated amino-acids to a soluble fraction of ribonucleic acid (RNA)[1]. Such reactions are also involved in the biosynthesis of some peptides, for example, the condensation of glutamylcysteine with glycine to give glutathione[2]. Enzymes activating almost all the naturally occurring L-amino-acids have been isolated from animal, plant, and microbial sources. Only one enzyme active on a D-amino acid, D-alanine, has been demonstrated in cells of *Lactobacillus arabinosus* and other Lactobacillaceae[3].

If the mechanisms for protein synthesis are involved also in the synthesis of peptides, it should be possible to demonstrate activation and transfer of amino-acids present in peptides but absent from proteins, such as many of the D-amino-acids. To test this hypothesis the following micro-organisms were selected, since they produce antibiotics containing one or more of the amino-acids that do not occur in proteins: *Penicillium chrysogenum P*–4 (Lepetit S.p.A.), producing penicillin that contains D-valine ; *Streptomyces antibioticus* 23 (Lepetit S.p.A.) and *Streptomyces parvus N.R.R.L. B*-1455 (both producing antibiotics of the actinomycin group in which D-valine, sarcosine, D-allo*iso*leucine and N-methyl-L-valine are present) ; *Bacillus polymyxa A.T.C.C.* 10401 and *B. polymyxa* 2459 (Ch. Pfizer and Co.) producing, respectively, polymyxin-D and polymyxin-B, containing D-phenylalanine, D-leucine, D-serine, D- and L-α,γ-diaminobutyric acid; *Bacillus circulans A.T.C.C.* 14040, producing circulin containing D-leucine and L-α,γ-diaminobutyric acid. The micro-organisms were grown on complex media capable of supporting antibiotic synthesis and were collected when the production of the antibiotic reached its maximum (2 days for the bacteria, 3 for *P. chrysogenum*, and 6 to 8 for the Streptomycetes). Cell-free extracts were prepared by suspending the centrifuged cells in one volume of 0·066 *M* phosphate buffer and 0·002 *M* reduced glutathione (*p*H 6·9) and disrupting them with glass beads in a refrigerated mechanical disintegrator. Following centrifugation at 20,000*g* for 20 min., the presence of amino-acid-activating enzymes was assayed on the supernatants by measuring the exchange between ATP and radioactive pyrophosphate[4].

The results (Table 1) indicate that, while a fair number of the L-amino-acids is activated, no activation of the D-amino-acids is detectable even if the micro-organism is capable of synthesizing compounds containing amino-acids with such an optical configuration. In addition, sarcosine, which has no optical activity, is not activated by the tested Streptomycetes. L-α,γ-diaminobutyric acid, which has not been found in proteins, is activated by strain 2459 of *B. polymyxa* ; this is the first time that this amino-acid is reported to be activated.

D-Valine	—	—	—	0	0	0
None (control)	0·133	0·280	0·355	0·507	0·073	0·100

The assay system contained 20 *μM* of *tris* buffer (*p*H 7·9); 5 *μM* of ATP (*p*H 6·5); 2·5 *μM* of $MgCl_2$; 3·2 *μM* of sodium pyrophosphate-phosphorus-32 (corresponding to approximately 340,000 counts per min. on a 'Tracerlab' mica window counter); 10 *μM* of amino-acid; cell-free extracts ranging from 0·068 to 0·49 mgm. of protein; glass distilled water, 0·5 ml.

The values obtained in the controls containing no amino-acids were subtracted from all the experiments. The activation was considered present when the experimental data were at least 10 per cent higher than the controls.

The possibility that the enzymes activating the D-amino-acids and sarcosine through an ATP-pyrophosphate exchange are destroyed during the process of extraction or are present in too small amounts for detection cannot be ruled out, but seems unlikely. It appears more probable that the pathway of biosynthesis of these peptides does not involve the activation of the D-amino-acids. Such a hypothesis is in agreement with the recent findings that exclude a process of amino-acid activation in the biosynthesis of some petides containing D-alanine and other L-amino-acids by *Staphylococcus aureus*[5]. Work under way in this laboratory[6] has shown that while D-leucine-^{14}C is incorporated in the polymyxin-D synthesized by *B. polymyxa*, the amino-acid is not activated by an ATP-pyrophosphate exchange nor transferred to soluble RNA.

We wish to acknowledge the kind release of cultures from Lepetit S.p.A., Milan, and Charles Pfizer and Co., Brooklyn, N.Y. This work has been supported by a grant of the International Institute for Scientific Research.

Enzymic Binding of Hydroxylamine by Fumaric Acid

AN organism similar to *E. coli* isolated in our laboratory was found to grow in a minimal medium containing glucose and ammonium sulphate in the presence of relatively large concentrations of hydroxylamine (up to 100 μgm./ml. of the hydrochloride—amounts which were highly toxic to other organisms). The amine, which was determined by the method of Csaky[1], was found to disappear during growth.

The metabolic conversion of hydroxylamine by the organism was measured using washed cell suspensions, lyophilized cells, or cell-free preparations purified by fractionation with ammonium sulphate and further treatment on a *DEAE*-cellulose column. The reaction mixture (for composition see Table 1) was incubated at a low *p*H of 5·6–5·8 in order to minimize spontaneous decomposition of the hydroxylamine.

When a sonicated cell-free extract of washed lyophilized cells was employed instead of living cells, very little, if any, hydroxylamine disappeared. The activity of the extract could, however, be restored by the addition of the wash fluid of the freshly lyophilized preparation, fumaric or malic acid. While succinate showed only slight activity, maleate and malonate were inactive. Some of the results are shown in Table 1. The rate of disappearance of hydroxylamine was dependent on the amount of fumaric or malic acid present. In fact, for each μmole of added fumarate (or malate) about 0·8–0·9 μmole of hydroxylamine was consumed[2]. Changes in the amounts of fumaric and malic acids were followed chromatographically[3].

Using aged lyophilized preparations (stored in the deep freeze at – 18° C.) disappearance of hydroxylamine could be achieved by the addition of fumaric but not malic acid. Thus, fumaric acid seems to be the active substrate, while the effectiveness of malic acid can be ascribed to the presence of a labile fumarase. This assumption was confirmed by adding citrate or phthalate buffer (50 μmoles–*p*H 5·8)[4] to the reaction mixture. Under these conditions only fumaric acid was active.

Ammonia, when added instead of hydroxylamine, did not react with fumaric acid (ammonia did not disappear), thus no aspartase seems to be involved. The presence of hydroxylamine reductase[5,6] can be ruled out as no ammonia, or very little, was formed. Nitrate, nitrite or gaseous nitrogen compounds were not found.

The reaction carried out with the purified enzyme was not activated by any of the following ions: Mn^{2+}, Mg^{2+}, Co^{2+}, Zn^{2+}, Fe^{2+}, PO_4^{3-}, or adenosine triphosphate (ATP). Diphosphopyridine nucleotide (DPN) (0·3 μmole) activated some purified enzyme preparations but not others. Sodium cyanide ($10^{-2}M$) or hydrazine ($10^{-2}M$) had no inhibiting effect on the reaction.

Identification of the enzymic condensation product of hydroxylamine with fumaric acid was attempted. At the end of the reaction (after 1–2 hr. at 37° C.) the complete system and the respective controls were subjected to hydrogenation in the Parr apparatus as follows: a minute amount of platinum oxide was added to 1 ml. of the reaction mixture acidified with hydrochloric acid to about *p*H 1·0 and shaken for 6 hr. under a pressure of 15 lb./in.². The hydrogenated samples were filtered and chromatographed in order to detect amino-acids. The complete system showed a spot of aspartic acid in contrast to the various controls (without enzyme, fumaric acid or hydroxylamine). The amount of aspartic acid formed by the catalytic hydrogenation was roughly comparable to the amount of hydroxylamine which disappeared. The formation of aspartic acid when most of the hydroxylamine and fumaric acid had disappeared concomitantly suggests that hydroxylamine as such combined with fumaric acid at one of the carbon atoms adjacent to the double bond. The nature of this compound, which seems a likely intermediate, had not as yet been established. Still to be demonstrated is whether or not this compound can be enzymically reduced to aspartic acid by extracts of this micro-organism.

A varying portion of the hydroxylamine which disappeared during the reaction (from insignificant amounts to about 50 per cent) could be recovered by boiling the reaction mixture for 10 min. with 6 *N* hydrochloric acid, and the hydroxylamine determined after neutralization. Thus, the formation of a bound hydroxylamine product, as found by Endres[7] in *Azotobacter* cultures, can be shown with our *E. coli* preparation. The variability in the extent of the hydrolysis may perhaps indicate the presence, in some preparations, of an additional intermediary product and labile enzyme.

Although the enzymic reaction was studied in detail only with organisms similar to *E. coli*, we have

MANSFIELD OIL-GAS PLANT FOR LABORATORIES' GAS SUPPLY

• *Reliable* • *Simple to Operate* • *Safe*

Provides a gas supply at a constant calorific value of 1,350 B.T.U.'s per cu. ft. produced from Light Diesel Oil, Gas Oil, Paraffin, or other suitable oils available at low cost.

Enables the efficient use of a full range of modern gas burning appliances in any part of the world. Ideal for glass blowing and gives perfect oxidizing or reducing flames with ordinary atmospheric burners.

For full particulars send details of estimated number of burners to be used.

Induced Increase in Resistance of *Entamoeba histolytica* to Fumagillin

ALTHOUGH there has been much work on *in vitro* effects of various amœbicidal agents on *Entamoeba histolytica*, I have not found any published data dealing with the induced increase in resistance of this protozoan to amœbicidal agents. The antiamœbic activity of fumagillin was first studied by McCowen *et al.*[1] and was confirmed by Hrenoff and Nakamura[2]. Many workers have since studied the clinical efficacy of fumagillin in amœbiasis[3–7]. The present work was undertaken to determine the activity of fumagillin against a number of newly isolated strains of *E. histolytica* from a variety of clinical infections. Also, an attempt was made to increase resistance of these strains to this highly active amœbacidal antibiotic. The main reason for using fumagillin in these experiments is that it is not antibacterial in activity and therefore this agent can be studied in cultures of amœbæ growing in association with a mixed bacterial flora. The associated bacteria are required because *E. histolytica* cannot be cultivated axenically consistently. Furthermore, use of fumagillin minimizes the indirect activity of the drug on amœbæ since the bacterial flora apparently are unaffected, and the inhibition of the amœbæ can be considered as directly due to the antibiotic.

Six strains of *E. histolytica* isolated approximately four months earlier were used. Two strains were isolated from human cases of intestinal amœbiasis, two strains from human cases of cutaneous amœbiasis, one strain from a case of hepatic amœbiasis, and one strain from a case of appendicitis due to *E. histolytica*. The amœbæ were cultured regularly on a medium consisting of a solid phase of egg and whole blood (a coagulated slant) overlaid with 5 ml. of Ringer solution. Rice powder was added just before inoculation of the media. The amœba cultures were transferred three times a week and incubated at 37° C. Amœbacidal concentrations of fumagillin were determined by growing the amœbæ in culture tubes containing varying concentrations of the agent. Control tubes not containing the antibiotic were also inoculated. The tubes were read after 48 hr. of incubation by removing approximately 0·1 ml. of the sediment from each tube, placing on a microscope slide, covering with a glass cover slip, and counting the numbers of amœbæ in the low-power field of the microscope. Ten different fields were counted and average counts recorded; two samples were taken from each tube. Each experiment was performed in quadruplicate and each experiment was repeated three or four times. The concentration of fumagillin necessary to produce 100 per cent inhibition (no detectable surviving amœbæ) was determined. Resistance to fumagillin was induced by growing the amœbæ in culture media containing concentrations of the antibiotic which produced 50 per cent inhibition. The amœbæ were grown on media containing antibiotic for 2 weeks, then the susceptibility to fumagillin was re-assayed to determine the new amœbacidal end-point. Strains of amœbæ which developed resistance were afterwards cultivated in media not containing the antibiotic for 2 weeks and re-tested for their sensitivity to fumagillin in order to determine the stability of the induced resistance.

Complete inhibition of *E. histolytica* by fumagillin was obtained by concentrations ranging from 0·01 μgm. to 100 μgm./ml., depending on the strains. The two strains obtained from two different cases of cutaneous amœbiasis possessed the highest resistance to the antibiotic; concentrations of 50–100 μgm./ml. were needed to produce 100 per cent inhibition. The strains obtained from cases of intestinal amœbiasis were the least resistant to fumagillin; 0·01–0·1 μgm./ml. of fumagillin produced 100 per cent inhibition. The strains isolated from a case of hepatic amœbiasis and a case of amœbiasis of the appendix were completely inhibited by 1–10 μgm./ml. of fumagillin. The cutaneous strains, which had the highest degree of resistance, were grown in the presence of 1–10 μgm./ml. of fumagillin and re-tested for their susceptibility to fumagillin. No increase in resistance was noted. However, when the two strains from the intestinal cases which possessed the least amount of resistance, were grown in the presence of 0·001–0·01 μgm./ml. of fumagillin, the resultant cultures were highly resistant to fumagillin. These more resistant strains required 75–100 μgm./ml. before 100 per cent inhibition could be obtained. These two strains retained this induced resistance to fumagillin in spite of cultivation in the absence of the antibiotic. Sufficient time was not available to determine the permanence of this resistance. The strains which possessed intermediate sensitivity to fumagillin, namely, those obtained from the liver and the appendix, also developed resistance to the drug. However, none of the strains developed resistance to the degree that would permit growth in the presence of more than 100 μgm./ml. of the antibiotic.

It appears that resistance to fumagillin can be induced more readily in strains which are more sensitive to this antibiotic. Furthermore, the level of resistance produced was high; for example, a 1,000- to 10,000-fold increase in resistance was induced in the strains isolated from the intestine. Although this resistance was maintained for a period of one and a half months, it would be desirable to determine its permanence. No adequate explanation can be given for the failure to induce resistance in the strains which were initially more resistant to the antibiotic. It is interesting that the induced resistance of the most susceptible strains reached a maximum which was approximately the concentration required to kill the most resistant (initially) strains. It is also interesting that the resistance induced in the intestinal strains was not gradual but a sudden maximal resistance. It is conceivable that in the case of fumagillin, at least, strains of *E. histolytica* isolated from different clinical materials have different degrees of susceptibility to this antibiotic. Admittedly, the number of strains studied could have been larger; however, the availability of amœba strains from cutaneous, brain, and extra-intestinal amœbiasis is limited.

VIROLOGY

Effect of *p*-Fluorophenylalanine on the Multiplication of Foot-and-Mouth Disease Virus

MANY amino-acid analogues are known to prevent protein synthesis. *p*-Fluorophenylalanine in particular has been shown to inhibit synthesis by competition with phenylalanine. The growth of several animal viruses is inhibited by the addition of this analogue to the growth medium (for example, the viruses of poliomyelitis[1], influenza[2], fowl plague[3] and Western equine encephalomyelitis[4]). In the case of poliovirus and influenza virus, the effect of *p*-fluorophenylalanine on the infectivity and hæmagglutinating activity, respectively, was studied. A more detailed examination of the effect of the inhibitor on the synthesis of the sub-units of fowl plague virus and Western equine encephalomyelitis virus has shown that information can be obtained on the manner in which the complete virus particles are formed. The present communication describes the effect of *p*-fluorophenylalanine on the synthesis of the infective component and viral ribonucleic acid of foot-and-mouth disease virus.

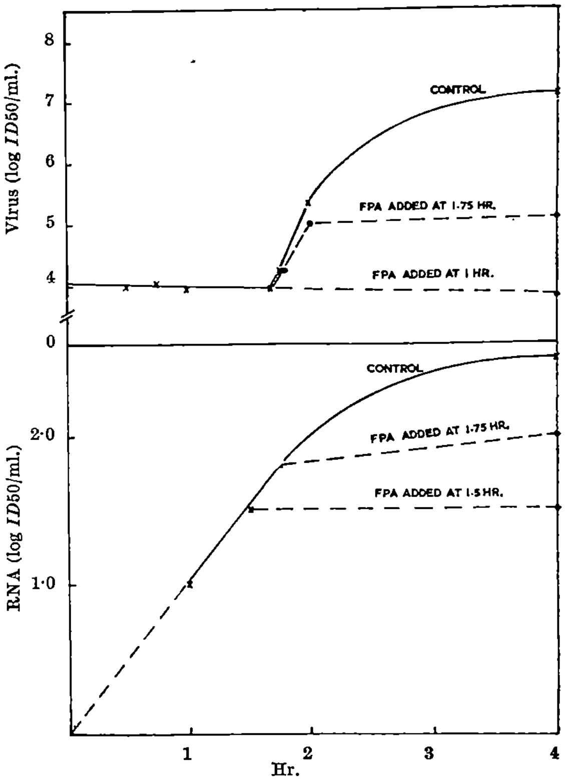

Fig. 1. Effect of adding 1,000 μ*M* *p*-fluorophenylalanine to infected cells at different times during growth cycle (this concentration completely inhibits virus synthesis)

Infection of pig kidney tissue culture cells with the virus (strain 997, type *C*) leads to the rapid production of new virus in the cells (Fig. 1). The formation of the infective viral ribonucleic acid, one of the precursors of the complete virus, precedes the appearance of the virus by 15–30 min. (ref. 5). It has previously been shown[6] that the inclusion of *p*-fluorophenylalanine in the growth medium reduces the yield of virus, the extent of the reduction depending on the concentration of the analogue. Table 1 shows some typical figures for the reduction of virus titre at 4 hr. when the suspending medium was phosphate-buffered saline containing 0·1 per cent glucose. The effect is not due to toxicity of the *p*-fluorophenylalanine, since it can be reversed by the addition of phenylalanine[6].

As the production of foot-and-mouth disease virus depends on the prior synthesis of its infective ribonucleic acid component, it seemed to be of interest to determine the effect of *p*-fluorophenylalanine on the production of the infective nucleic acid. The figures in Table 1 show that the reduction in yield of infective ribonucleic acid obtained from infected cells inhibited by *p*-fluorophenylalanine corresponded with the fall in virus titre. It seems likely, therefore, that the formation of the precursor infective nucleic acid is in some way connected with a protein the synthesis of which is inhibited by the analogue. With phage, the early inhibition of protein synthesis prevents the formation of phage nucleic acid, since specific enzymes[7,8] must be induced to synthesize the hydroxymethyl cytosine base prior to incorporation in the nucleic acid. Once these enzymes are formed, inhibition of protein synthesis does not prevent the production of phage nucleic acid, although complete phage particles are not formed. This does not appear

Table 1. YIELD OF VIRUS AND VIRAL RIBONUCLEIC ACID AT 4 HR. IN PIG KIDNEY TISSUE CULTURE CELLS WITH *p*-FLUOROPHENYLALANINE

Concentration of *p*-fluorophenylalanine (μ*M*)	Virus titre (mouse log *ID*50/ml.)	Ribonucleic acid titre (log *ID*50/ml.)
0	6·9	2·7
50	5·9	2·0
100	5·5	1·0
150	5·4	1·0
500	4·0	—

Titre of infected cells at time 0: $10^{4·3}$ *ID*50/ml.

to be the case with foot-and-mouth disease virus, as the addition of p-fluorophenylalanine (1,000 μM), even immediately before the maturation stage, leads to complete inhibition of infective virus and viral nucleic acid synthesis within 20 min. (Fig. 1). Even for natural amino-acids it has been reported that 15 min. is required for 75 per cent penetration[9], so 20 min. probably represents the time required for p-fluorophenylalanine to reach its site of inhibition.

It appears, therefore, that the synthesis of the infective nucleic acid of foot-and-mouth disease virus, like that of Western equine encephalomyelitis virus[4], is intimately related to the continuous synthesis of protein. This might be due to the need for the continuous synthesis of induced enzymes or to the fact that ribonucleic acid and protein synthesis are intimately coupled, as has often been postulated[10].

Leaf Curl Virus and the Flavonoid Content of Resistant and Susceptible Strains of Cotton

Massey and Andrews[1] reported finding larger amounts of unidentified 'brown' pigments in aqueous extracts obtained from healthy cotton leaves than in those obtained from leaves infected with cotton leaf curl. By means of the known chemical tests I ascertained that the pigments are in fact anthocyanins. The work described here is a study of the changes in the amounts of various flavonoids in leaves of resistant and susceptible strains of cotton, in the course of infection.

Top leaves from two strains of Domains Sakel were used, *BAR* 14/25 as a highly susceptible strain and *X*17/30 *A* as a strain resistant to leaf curl virus. Both strains were grown in the same plot and were cultivated under identical conditions. It was observed that virus infection appeared in the susceptible strain (*BAR* 14/25) thirty days after sowing and 100 per cent infection had occurred 115 days after sowing. Infection started in the resistant strain (*X*17/30 *A*) 70 days after sowing and only 40 per cent infection was observed 120 days after sowing.

Leaf extraction and methods of determining total phenols, anthocyanins, leuco-anthocyanins, and flavanols were those used by Swain and Hillis[2].

The results (Table 1) show that the percentages of total phenols, leuco-anthocyanins and flavanols are higher in the resistant than in the susceptible strain throughout the season. Infection with the virus caused a rise in the amounts of total phenols, leucoanthocyanins and flavanols in both strains, followed in all cases by a gradual decrease in these amounts.

Table 1. Phenolic Compounds in Cotton Leaves in the Course of Infection with Leaf Curl Virus
(Percentage on dry weight basis)

Days after sowing	Total phenols		Anthocyanins		Leucoanthocyanins		Flavanols	
	H	I	H	I	H	I	H	I
	BAR 14/25 (Susceptible)							
40	7·01	8·74	1·22	1·34	0·03	0·06	0·16	0·20
60	5·14	6·97	0·93	1·24	0·03	0·05	0·17	0·21
80	6·54	4·56	0·68	0·72	0·08	0·05	0·30	0·23
100	5·61	3·32	0·55	0·52	0·07	0·04	0·28	0·21
	X 17/30 *A* (Resistant)							
40	10·06	—	1·66	—	0·08	—	0·24	—
60	9·22	—	1·42	—	0·09	—	0·30	—
80	7·26	10·47	1·23	0·91	0·19	0·75	0·43	1·55
100	7·83	4·26	0·89	0·41	0·27	0·09	0·56	0·22
120	6·56	1·89	0·83	0·23	0·23	0·09	0·43	0·29

H, healthy; I, infected

The anthocyanins behaved in the same manner in the susceptible strain, that is, there was a sharp rise in the amounts following infection, then a gradual decrease, but in the resistant strain these amounts actually decreased rapidly after infection had occurred.

The results obtained in this work suggest that there might be some connexion between the flavonoid content of the leaves and the resistance of cotton plants to leaf curl virus. A study of the flavonoid content may act as a guide in spotting resistant strains in the course of breeding for resistance towards this disease.

This work was carried out in the Faculty of Agriculture, University of Khartoum; I am indebted to Dr. T. Swain of the Low Temperature Research Station, Cambridge, for his help.

SOIL SCIENCE

Isolation of Anthraquinone from Humus

It is now generally accepted that the skeletal part of humic acids consists of heteropolycondensates of various aromatic nuclei. This concept, however, has been deduced rather indirectly from physico-chemical data such as X-ray analysis, and benzene seems to be the sole aromatic ring identified by the method of organic chemistry[1]. Recently we found anthraquinone in the decarboxylation products of the water-soluble acid fraction obtained by the alkaline permanganate oxidation of humic acids.

The humic acids used in this work belonged to so-called *A* type[2], and were obtained from a volcanic ash soil at the foot of Mt. Fuji, and from a muck soil presumably formed under the influence of volcanic ash showers on low-moor peat at Tanemori, Akita Prefecture, both soils being treated with 0·5 per cent sodium hydroxide at 100° C. for 30 min.

The sample, dissolved in N potassium hydroxide, was heated at about 90° C. and oxidized by adding potassium permanganate powder in small portions, until the permanganate to humic acid ratio became 4·0. The mixture was cooled, filtered to remove the precipitated manganese dioxide, and washed thoroughly with water. The filtrate was slightly acidified with sulphuric acid and concentrated under reduced pressure.

After the removal of inorganic salts and acid-insoluble organic acids by filtration, the reddish-brown solution, adjusted to contain about 4 *N* sulphuric acid, was subjected to ether extraction for many days. The extract, composed mainly of polycarboxylic acids, was freed from ether by evaporating to dryness, and the reddish-brown solid was obtained, which was decarboxylated by the copper-quinoline method of Montgomery and Holly[3].

The distillate during decarboxylation was collected in ethyl alcohol, in which the presence of benzene was confirmed by its ultra-violet spectrum ; pyridine was also detected.

The dark-coloured residue from the decarboxylation was mixed with ether, filtered through a filter paper to remove insoluble materials, and washed with hydrochloric acid (1 : 1) and 5 per cent sodium hydroxide successively to remove basic and acid fractions, respectively. The neutral fraction was then freed from ether by evaporating to dryness, and after drying in a desiccator containing silica gel, dissolved in small quantities of carbon tetrachloride.

The carbon tetrachloride solution was chromatographed through an alumina column. By developing it with carbon tetrachloride, a yellow band moved down, giving at first colourless, then yellow filtrates. Development was continued until the yellow band passed through the column and the filtrate became nearly colourless. This filtrate was passed through a silica gel column. The top of the silica gel column (fraction 3) was stained strongly reddish-brown, the other part of the column (fraction 2) colourless, and a colourless filtrate was obtained (fraction 1). Fractions 3 and 2 were scraped separately, and eluted with ether.

Three fractions could be distinguished under ultra-violet light on the alumina column after development ; the upper layer (fraction 6) being dark brown in appearance and showing no fluorescence, the middle layer (fraction 5) yellowish brown and yellowish green fluorescence, and the under layer (fraction 4) grey and partly red fluorescence. These fractions were scraped out separately, and eluted with acetone. Fractions 5 and 6 were reserved for further investigation.

Fractions 1–4 were tested for aromatic compounds by examination of infra-red and ultra-violet spectra, besides routine organic analysis. The results obtained so far may be summarized as follows :

First it must be mentioned that yellow crystals were readily obtained from fractions 3 and 4 by evaporating the eluates. Needle-shaped crystals obtained by recrystallization from ethyl alcohol followed by sublimation were identified as anthraquinone, because its melting point was 285° C. and this was not depressed by mixing with authentic specimen, and the infra-red spectrum was identical with that of anthraquinone.

Fraction 1 was considered to be mainly composed of paraffins, but the ultra-violet spectrum showed small quantities of naphthalene derivatives to be present. In the case of Fuji humic acid, 2-methyl-naphthalene was confirmed by its ultra-violet spectrum and the melting point of its picrate (115–116° C.). The presence of naphthalene derivatives in fraction 2 was also presumed.

From these results, though very qualitative, it is reasonable to suppose that humic acids showing a higher degree of humification contain not only a benzene ring but also anthracene, probably in the form of anthraquinone and naphthalene rings.

Differences in the nature and properties of humic acids obtained from various soils may be explainable by the composition of their aromatic nuclei. Further investigations are proceeding.

PSYCHOLOGY

Measuring Visual Constancy for Stationary or Moving Objects

IF two objects of the same size are viewed so that one is twice as far from the eyes as the other, the retinal image of the farther object will be one-half the size of the image of the nearer object, but it does not appear half the size to the observer. They both appear almost the same size and the effect, which is due to perceptual interpretation of the retinal image, is known as size constancy[1,2].

In this method of measuring constancy of size, the eye is placed close to a small light-source which casts the shadow of an object (such as a flat disk) on a vertical screen. The angle subtended at the eye by the shadow will remain constant for any distance of the screen, but the shadow appears to expand as the screen on which it is projected is moved away from the observer. Other positions of the eye in relation to the source will produce size changes in the retinal image when the screen is moved. With the eye nearer the screen, the retinal image will contract (Fig. 1) ; with the eye behind the source it will expand. The degree of size constancy may be described in terms of the Thouless ratio, which is given by :

$$\log \frac{d_2 l_1}{d_1 l_2} \Big/ \log \frac{d_2}{d_1}$$

where d_1 and d_2 are distances of the screen from the eye when the shadow measures l_1 and l_2 respectively, the position of the eye being such that no size change is observed.

One can also measure constancy of shape, this being the tendency for a flat object to have a perceived

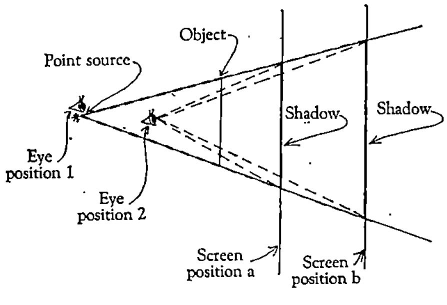

Fig. 1. Angle subtended at eye by shadow with eye in position 1 is constant for varying positions of screen ; with eye in position 2, angle subtended decreases as screen moves from position *a* to position *b*

shape corresponding very nearly to its normal projection ('normal' in the geometrical sense). If the screen is rotated around its vertical axis while the shadow-casting object remains stationary, the shadow appears to enlarge horizontally. Although the shadow on the screen changes shape, the retinal image is unaltered. The shape perceived is nearly that of the shadow viewed normally.

The magnitude of this effect can be measured, again using a null method, by arranging for a compensatory change of shape of the retinal image. This may be done by rotating the (flat) object. The screen and object may be linked to provide simultaneous rotations, their relative angles of rotation being adjustable. The magnitude of the effect may again be stated in terms of the Thouless ratio, which is given by :

$$\frac{\log P - \log S}{\log R - \log S}$$

where R is the ratio of the width of the shadow on the screen to its height, P the ratio of perceived width to perceived height (arranged to be constant and measured when the screen is normal to the observer), and S the ratio of the retinal width of the shadow to the retinal width when the screen is normal. If the angles subtended at the eye are small, the Thouless ratio is given by $\frac{\log \cos p}{\log \cos q}$, where p is an angle turned through by the object and q the corresponding angle turned through by the screen (Fig. 2), the relative angles of rotation being such that no change of shape is observed.

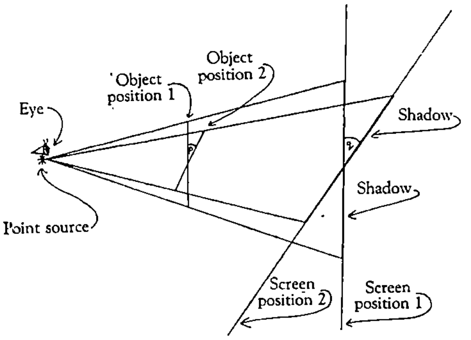

Fig. 2. With eye as close as possible to source, relative angles of rotation are adjusted until no change in shape observed

We are using this shadow method to investigate constancy during movement, which should be important in considering perceptual judgments involved in flying or driving. In particular we have tried to discover whether apparent movement due to constancy can be adapted. It is known that continuous presentation of real movement gives rise to an after-effect of apparent movement in the opposite direction[3]. The question here is: Can apparent expansion or contraction of the shadow produce an after-effect ? By projecting the shadow on a series of screens which move continuously away from the observer and are stopped after 1 min., we find that an after-effect does take place, though the retinal image of the shadow remains unchanged during the movement of the screens. During the movement the shadow appears to expand ; in the after-effect, it appears to contract. An after-effect of movement can thus be produced without shift of the image across the retina. Observation of the moving screens without the shadow does not produce the same after-effect of contraction of the shadow thrown on the screen now stationary, so the after-effect is not merely an induced movement, as described by Duncker[4].

One of us (S. M. A.) is in receipt of a Department of Scientific and Industrial Research studentship, and another (C. D. S.) of a grant from the Medical Research Council, which also provided support for apparatus.

ANTHROPOLOGY

The Juvenile Mandible from Olduvai

FURTHER to my report in *Nature* on February 25, p. 649, about the new discoveries of hominid remains in Bed I and Bed II at Olduvai Gorge, additional information can be given on the mandible of the juvenile from the site *FLK.NN*.I, at a horizon older than that of *Zinjanthropus*.

The third lower premolar (often called the first lower premolar by anatomists) is, in all the published Australopithecines, markedly shorter mesio-distally than wide bucco-lingually. The published figures for fully erupted lower third premolars of Australopithecines in South Africa include 14 from Swartkrans with indices $(100 \times L)/B$ ranging from 76·00 to 91·9 and a mean of 83·2. Kromdrai has only one reasonably preserved third lower premolar with an index of 83·2. Sterkfontein has only two good measurable examples published, which give indices of 77·8 and 76·8 respectively. Makapan has two measurable teeth, and the indices are said to be identical, at 88·4.

It is thus clear that, on the basis of the available published data (which are confirmed by my own observations on the original material at Pretoria and Johannesburg, which Prof. R. A. Dart, Prof. P. V. Tobias and Dr. J. T. Robinson kindly allowed me to examine), the third lower premolars of all known Australopithecine specimens are broader bucco-lingually than they are long mesio-distally. The index $(100 \times L)/B$ gives a range of 76·00–91·9.

In the juvenile hominid from the level below *Zinjanthropus* of site *FLK.NN*.I the measurements of the third lower premolars are as follows :

	Length	Breadth	Index
Left	11.00	9·5	115·8
Right	11·00	9·5	115·8

Thus, while all the published length–breadth indices of fully erupted lower third premolars of all *Australopithecus* and *Paranthropus* specimens are much less than 100 (that is, broader than long) and have a range of 76·00–91·9, the indices of the tooth in the juvenile hominid from the pre-*Zinjanthropus* level are greater than 100, being in fact 115·8.

Quite apart from this very clear measurable difference which puts the third lower premolar completely out of the known range of measurable

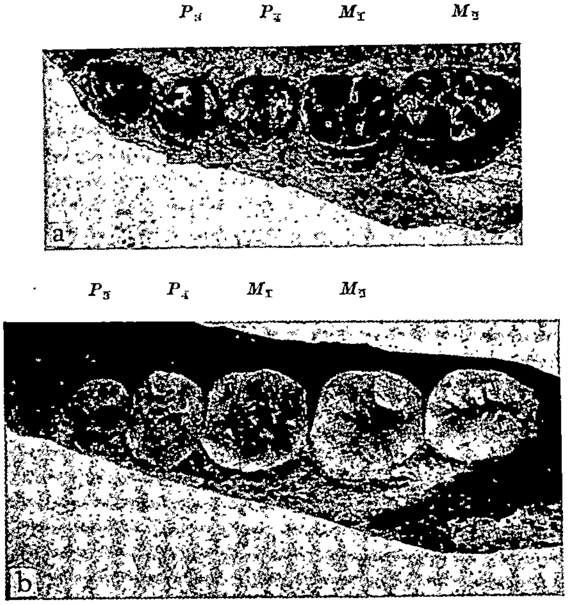

Fig. 1. Comparison between the teeth of the left side of the (*a*) pre-*Zinjanthropus* juvenile mandible with those of (*b*) an adult *Paranthropus* to show the morphological differences. In the Olduvai specimen the third molar is not present. (Not to the same scale, but reduced so that the length $P_{\overline{3}} - M_{\overline{2}}$ inclusive is approximately the same so as to show relative proportions)

variation in the Australopithecines, the morphological picture is also completely different from that of any Australopithecine that I have been able to examine, or of which there are published photographs available to me (Fig. 1).

Turning next to the published data of lower fourth premolars (second premolars of some anatomists) of known Australopithecines, we find that there are 13 measurable specimens from Swartkrans, all of which are much wider bucco-lingually than they are mesio-distally. The index (100 × *L*)/*B* ranges from 61·1 to 91·1 with a mean of 82·3 (very close to the mean for the third lower premolars). Only two specimens from Kromdrai are known and they fall well within the range with indices of 84·4 and 84·7. Only two Sterkfontein lower fourth premolars appear to have been described in the literature, and these give indices of 87·0 and 82·9. I know of no measurable fully erupted fourth lower premolars from Makapan that have been recorded; the known specimens are either not fully erupted or very worn and damaged.

When we turn to the juvenile hominid from the pre-*Zinjanthropus* level at *FLK.NN*.I, we find that the fourth premolars are markedly longer mesio-distally than they are bucco-lingually. The measurements and indices are as follows:

	Length	Breadth	Index
Left	11·0	10	104
Right	11·0	10·50	104·7

Thus we find that whereas in the known Australopithecines the range in the index (100 × *L*)/*B* is from 61·1 to 91·1, in the juvenile from the pre-*Zinjanthropus* level at Olduvai, the position is quite different. The mesio-distal length is greater than the bucco-lingual width, so that the indices are more than 100.

Again, apart from measurable differences, the fourth premolars in the new jaw are morphologically different from those I have seen in the collections of Australopithecines at Johannesburg and Pretoria (Fig. 1).

The published data on the first lower molars of *Australopithecus* shows that the index (100 × *L*)/*B* varies from 114·6 in one of the Sterkfontein specimens to 100·8, also from Sterkfontein, and the indices from other sites fall within this range, both in respect of *Australopithecus* and *Paranthropus*. The first lower molars in the juvenile jaw from the pre-*Zinjanthropus* level show identical measurements of length 14·25 and breadth 12·00, giving an index of 117·00. This is outside the published range of variation of Australopithecine first lower molars. Morphologically, too, there are differences in the crown pattern, which is much simpler and more like that which can be observed in some modern Australian Aborigine teeth.

The second lower molar of the pre-*Zinjanthropus* juvenile is 16·00 mm. long and 14·00 mm. wide. In this case, the index falls within the range of variation of the known Australopithecines. Some morphological differences seem to me to be present, but need further study. I do not recall (nor have I notes on) any really comparable tooth in the collections in Pretoria or Johannesburg, but I say this with reservations.

There is a single upper molar (which appears to be an unerupted upper molar) in which the roots have not yet formed and in which the crown is completely fresh. It seems likely that it represents the third upper molar of the same juvenile as is represented by the mandible, and in which the lower second molar is erupted but scarcely worn.

If this tooth is correctly interpreted as an unerupted third upper left molar, then it confirms my view that the teeth of the juvenile pre-*Zinjanthropus* differ, in most measurable respects, from the Australopithecines. The tooth has a mesio-distal length of 13·5 and a bucco-lingual width of 12·75, giving an index of (100 × *L*)/*B* of 106, which seems to be outside the range of variation published for any Australopithecine upper third molar. Even if it is not a third upper molar but a second, it is still outside a published range, while morphologically it does not seem to be of Australopithecine type.

In conclusion, may I say that when I used the word 'child' with reference to the pre-*Zinjanthropus* juvenile in my report in *Nature* of February 25, I was not intending thereby to imply that the father was a 'man' in the sense of the accepted definition of treating him as the 'maker of tools to a set and regular pattern'. I used the word 'child' simply as meaning a juvenile of the family Hominidae.

There are stone tools and a bone tool in direct association with the juvenile, but it is not yet certain whether his family made these tools, any more than it is quite certain that *Zinjanthropus* made the tools which are in direct association with the skull from *FLK*.I.

If I am right in believing that the juvenile from *FLK.NN*.I is not an Australopithecine, but a very remote and truly primitive ancestor of *Homo*, then it is possible (and I stress the fact here that I only use the word 'possible' at this stage of the inquiry) that it was this branch of the Hominidae that also made the Oldowan tools at the site *FLK*.I where *Zinjanthropus boisei* was found. We do not yet know the final truth of this problem.

L. S. B. Leakey

The Coryndon Museum,
Box 658, Nairobi,
Kenya.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Biochemists (2) (science graduates, preferably with experience in medical biochemistry), for duties involving laboratory work in clinical pathology at Foresterhill or at Woodend Hospital—The Secretary, The University, Aberdeen (July 27).

Animal Physiologist (with research experience), to develop work in the field of adaption of animals to environment—The Secretary, Animal Breeding Research Organization, A.R.C., Glenbourne, South Oswald Road, Edinburgh 9 (July 29).

Lecturer or Assistant Lecturer in Organic Chemistry—The Registrar, The University, Manchester 13 (July 31).

Lecturer in Psychology at Victoria University of Wellington, New Zealand—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, August 4).

Lecturer (preferably with research experience in surface chemistry or chemical kinetics) in Pharmacy at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 11).

Lecturer (graduate in science or engineering) in the Department of Building Science—The Registrar, The University, Liverpool (August 12).

Research Assistant (with a higher degree in theoretical physics or mathematics) in Theoretical Physics—The Registrar and Secretary, King's College (University of Durham), Newcastle-upon-Tyne 1 (August 12).

Fellow (specialized in organic chemistry, with special reference to the chemistry of compounds of neuropharmacological significance) in the Department of Physiology, John Curtin School of Medical Research, Australian National University—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (August 14).

Physical Research Chemist (physical chemist, preferably with several years' postgraduate experience), for work concerned with fundamental studies on gelation—The Director of Research, British Gelatine and Glue Research Association, 2a Dalmeny Avenue, London, N.7 (August 14).

Lecturer or Assistant Lecturer in the Department of Applied Mathematics—The Registrar, The University, Liverpool (August 15).

Lecturer/Senior Lecturer (preferably with research interests in epidemiological or immunological aspects) in Parasitology in the Faculty of Rural Science, University of New England, Armidale, New South Wales, Australia, to teach and carry out research in parasitology with particular reference to livestock aspects—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 15).

Research Assistants (2) (with at least a B.Sc. degree or equivalent, and a special interest in physical chemistry or chemical engineering) in the Department of Chemistry, to continue a study of the equilibrium properties of imperfect gases under the terms of a contract between the University and the D.S.I.R.—The Registrar (Room 22, O.R.B.), The University, Reading (August 15).

Senior Technician or Technician (with the A.I.S.T. or equivalent qualification) in the Department of Zoology, University of Khartoum—The Registrar, University of Khartoum, c/o Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 15).

Textile Technologist (man or woman, with a first- or second-class honours degree in textile technology, chemistry or physics, or Associate or Fellow of the Textile Institute, or equivalent qualifications) at the Tropical Products Institute, London, W.C.1, to supervise a group concerned with research into, and laboratory examination of, various aspects of animal and vegetable fibres, pulp, paper and board-making materials, hides, skins, etc., of tropical origin—Civil Service Commission, 17 North Audley Street, London, W.1), quoting Ref. No. S/5333/61 (August 15).

Lecturer or Assistant Lecturer (with experience and research interests in plant physiology) in Botany at the University College of Rhodesia and Nyasaland—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 20).

Lecturer in Mechanical Engineering—The Registrar, Trinity College, Dublin 2 (August 28).

Reader in Aeronautics at Imperial College—The Academic Registrar, University of London, Senate House, London, W.C.1 (August 29).

Director of the Natural History Museum, Adelaide, South Australia—The Agent-General for South Australia, 56 Strand, London, W.C.2 (August 31).

Keeper of Scientific Books (with considerable experience of university or research library administration and a good honours degree preferably in science), to superintend the Radcliffe Science Library—The Librarian, Bodleian Library, Oxford (August 31).

Lecturer in Philosophy at the University of Canterbury, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, August 31).

Lecturers (3) in Chemistry at the University of Auckland, New Zealand—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, August 31).

Reader (with a special interest in the properties of materials) in Electrical Engineering at Imperial College—The Academic Registrar, University of London, Senate House, London, W.C.1 (August 31).

Lecturer in the Department of Medical Physics—The Secretary, Royal Free Hospital School of Medicine (University of London), 8 Hunter Street, London, W.C.1 (September 1).

Senior Lecturer in Applied Electronics at Victoria University of Wellington, New Zealand—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, September 1).

Lecturer or Assistant Lecturer (medically or non-medically qualified candidate) in the Department of Histology—The Registrar, The University, Liverpool, quoting Ref. CV/N (September 4).

Lecturer or Junior Lecturer in Pure Mathematics—The Registrar, Trinity College, Dublin 2 (September 4).

Lecturer in Social Anthropology at the University of Auckland, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, September 8).

Lecturer/Senior Lecturer (well qualified in electrical engineering or physics, general experience in electronics and a considerable detailed knowledge of solid state devices and circuits) in Electrical Engineering at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 15).

Senior Lecturer in Physics at Victoria University of Wellington, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, September 30).

Assistant Lecturer (with an honours degree or an honours diploma in technology in applied physics, and preferably research or industrial experience in some branch of applied physics) in Physics—The Secretary, Northampton College of Advanced Technology, St. John Street, London, E.C.1.

Biochemist (with a first- or second-class honours degree or graduate member of the Royal Institute of Chemistry), for duties in the Hæmatological Laboratory—The House Governor, King's College Hospital, Denmark Hill, London, S.E.5.

Lecturer or Assistant Lecturer (particularly interested in petrology and mineralogy) in Geology—Prof. D. Williams, Geology Department, Imperial College of Science and Technology, London, S.W.7.

Lecturer (preferably with a higher degree and research experience in an industrial environment) in Metallurgy in the Department of Materials—The Recorder, College of Aeronautics, Cranfield, Bletchley, Bucks.

Lecturer (university graduate in physics with industrial and/or research experience in radiation protection or a kindred subject, and preferably some teaching experience) in Physics—The Clerk to the Governing Body, Borough Polytechnic, Borough Road, London, S.E.1.

Physicists or Electrical Engineers (with experience in one or more of the following fields: high vacuum; R.F. techniques (75 Mc./s.); high power rectifier and pulse circuits; or general electronic instrumentation and controls), to assist with the construction and commissioning of a large heavy ion linear accelerator—The Assistant Director, Linear Accelerator Laboratory, Physics Department, The University, Manchester 13.

Postgraduate Student (recent graduate with a good degree in physics or physical chemistry) in the Department of Physics, to research under the supervision of Dr. J. G. Powles on some aspect of magnetic resonance—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1.

Research Assistant (recent graduate in chemistry with an interest in zoology or comparative biochemistry), to join a team investigating chemical constituents of the biles of many species, with a view to a fuller understanding of evolutionary theory and taxonomic principles—Prof. G. A. D. Haslewood, Biochemistry and Chemistry Department, Guy's Hospital Medical School, London Bridge, London, S.E.1.

Research Assistant (recent physics graduate) in the Department of Physics, for track analysis in connexion with the National Bubble Chamber project—The Assistant Registrar (Science), The University, Edgbaston, Birmingham 15.

Scientific Officer (with a first- or second-class honours degree in chemical engineering or in chemistry, and postgraduate training or experience in chemistry) at the Humber Laboratory, Kingston-upon-Hull, Yorkshire, to work on problems of both fundamental and applied research concerned with fish-smoking; the transport of fresh and frozen fish; and the manufacture of fish meal—The Director, Torry Research Station, D.S.I.R., Aberdeen, quoting Ref. Torry 8Z.

Senior Lecturer (graduate in pharmacy or chemistry with an established interest in the medicinal field) in Medicinal Chemistry at the Department of Pharmacy—The Secretary, The Royal College of Science and Technology, George Street, Glasgow, C.1.

Senior Lecturer (with a good university degree in agriculture or veterinary science, considerable postgraduate experience in research and/or teaching in a higher institution, and conversant with tropical work in animal husbandry) in Animal Husbandry in the School of Agriculture, Kumasi College of Technology, Ghana—The Assistant Registrar, Kumasi College of Technology, 29 Tavistock Square, London, W.C.1.

Senior Research Assistant (with a Ph.D. or appropriate research experience) in the Department of Physics, The University, Leeds 2.

Senior Research Associates (2) (experienced electrical engineers or physicists) in the Department of Physics, for the development of the proton synchrotron—The Assistant Registrar (Science), The University, Edgbaston, Birmingham 15.

Technical Officer (with a degree or National Diploma in Agriculture or a degree in agricultural botany), to assist in work on herbage seed production—The Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge.

APPOINTMENTS VACANT

AUSTRALIAN NATIONAL UNIVERSITY

INSTITUTE OF ADVANCED STUDIES

SENIOR FELLOWSHIPS IN MICROBIOLOGY

Applications are invited for two Senior Fellowships in the Department of Microbiology of the John Curtin School of Medical Research, which carries out research in virology. (Head of Department: Professor F. J. Fenner, F.R.S.) An applicant will be expected to have made substantial independent contributions to his field of knowledge and to be capable of supervising research students and post-doctoral fellows. For one post a man is required who has had research experience in studies on the pathology and pathogenesis of viral infections of animals. The other post is designed for work in viral biochemistry. Adequate laboratory facilities exist in the Department and the School for advanced work in both these fields. The salary range of a Senior Fellowship is from £A.3,000 to £A.3,550; increments are £A.90 per annum. A successful applicant will, in the first place be appointed at a salary and incremental limit fixed by reference to his standing and experience. Appointment is made for an initial period of five years; thereafter it may be made permanent. A Senior Fellow is entitled to one year's study leave on full pay, plus a contribution towards travel and other expenses, in every six years. Superannuation is on the F.S.S.U. pattern. Reasonable travel expenses are paid and assistance with housing is provided.

Further details should be obtained from the Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1. Applications close in Australia and London on September 15, 1961. Successful applicants will be notified as soon as possible thereafter.

UNIVERSITY OF ADELAIDE

TECHNICAL OFFICER OR SENIOR TECHNICAL ASSISTANT

Applications are invited for the above-mentioned appointment in the Department of Botany. Salary scales: Technical Officer (male), £A.1,385 by £A.45 to £A.1,745, with a bar at £A.1,565; (female), £A.1,040 by £A.33 15s. to £A.1,310, with a bar at £A.1,175; Senior Technical Assistant (male), £A.1,335 by £A.35 to £A.1,580; (female), £A.1,003 by £A.26 to £A.1,185. Qualifications: Considerable laboratory experience and competence with apparatus and techniques in biology, and preferably with the preparation and collection of botanical teaching materials and histological methods. Duties: Supervision of basic laboratory apparatus and preparation of undergraduate classes. General: (a) No provision is made for travelling expenses, but arrangements could be made to help a candidate from the United Kingdom to secure an assisted passage under the Commonwealth Migration Scheme. (b) Preference will be given to a qualified male applicant, but women also are invited to apply. (c) Any further information desired will be supplied on request to the Registrar.

Applications, giving particulars of qualifications and experience, marital status, the names and addresses of two referees, and the time when the applicant would be free to assume duty, should be sent to the Registrar, The University of Adelaide, Adelaide, South Australia, not later than August 31, 1961.

MAKERERE UNIVERSITY COLLEGE

EAST AFRICA

Applications are invited for the following appointments in the Faculty of Agriculture: (i) Readership or Senior Lectureship in Agricultural Chemistry. (ii) Lectureship in Agricultural Chemistry. (iii) Lectureship in Animal Husbandry. Salary scales: Reader, £1,974 by £75 to £2,724 per annum; Senior Lecturer, £1,950 by £75 to £2,475 per annum; Lecturer, £1,350 by £51 to £1,707 by £72 to £1,851 by £75 to £2,151 per annum. Entry point according to qualifications and experience. F.S.S.U. Child allowance £50 per annum per child (maximum £150 per annum). Passages for appointee and family (up to five adult passages) on appointment, termination and leave (three months every 21 months). Rent according to quarters provided £45 to £84 per annum (including basic furniture).

Detailed applications (six copies), naming three referees, by September 15, 1961, to Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1, from whom further particulars may be obtained.

METALLURGISTS

and

PHYSICISTS

required by the

CENTRAL ELECTRICITY GENERATING BOARD RESEARCH LABORATORIES

(Materials Division, Leatherhead, Surrey)

Advancing conditions in steam generation necessitate fundamental and applied investigations into the behaviour of ferritic and austenitic steels at high temperatures under complex stress systems. Successful candidates will join teams working on problems associated with creep, fatigue, phase changes, erosion and oxidation. Post-graduate industrial or university experience in one of these fields is desirable but not essential. Excellent facilities for research are available and publication of results is encouraged.

These posts have arisen solely through a decision to increase our activity in these fields.

Applicants (preferably under 26 years of age) should possess a good honours degree or equivalent qualification. There are also a few vacancies for staff who are slightly less qualified academically, but who have particularly relevant experience.

● Salaries up to £1,325 per annum (or higher in exceptional cases) will be fully commensurate with responsibilities, experience, ability and qualifications, and excellent prospects exist for promotion to higher grades.

Applications stating age, qualifications, experience, present position and salary, to the Appointments Officer, 24/30, *Holborn, London, E.C.*1, *by July* 31. *Quote " Ref. N/*315."

UNIVERSITY COLLEGE OF THE WEST INDIES

FACULTY OF AGRICULTURE

(IMPERIAL COLLEGE OF TROPICAL AGRICULTURE)

TRINIDAD, THE WEST INDIES

Applications are invited for (a) Lectureship or (b) Assistant Lectureship in Soil Science. Knowledge of tropical soils desirable. Salary scales: (a) £1,050 by £50 to £1,400 by £75 to £1,850 per annum; (b) £800 by £50 to £950 per annum, plus local allowance of £250 per annum (pensionable). Entry according to qualifications and experience, but in case of Assistant Lecturers and Lecturers below merit bar consideration is given to age in fixing salary. Child allowance. Settling-in allowance. F.S.S.U. Unfurnished accommodation at rental of 10 per cent of basic salary. Up to five full passages on appointment, normal termination, and triennial study leave.

Detailed applications (six copies), naming three referees, by August 14, 1961, to Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1, from whom further particulars may be obtained.

UNIVERSITY OF MANCHESTER

Applications are invited for the post of Lecturer or Assistant Lecturer in Organic Chemistry in the Faculty of Science. Duties to commence as soon as possible. Salary scales as follows: Lecturer, £1,050 to £1,850 per annum; Assistant Lecturer, £800 to £950 per annum. Membership of F.S.S.U. and children's allowance scheme.

Applications should be sent not later than July 31, 1961, to the Registrar, the University, Manchester 13, from whom further particulars and forms of application may be obtained.

UNIVERSITY OF LONDON

READERSHIP IN AERONAUTICS AT IMPERIAL COLLEGE

The Senate invite applications for the Readership in Aeronautics tenable at Imperial College (salary scale £1,675—£1,975—£2,425 a year plus £80 London allowance).

Applications (10 copies) must be received not later than August 29, 1961, by the Academic Registrar, University of London, Senate House, W.C.1, from whom further particulars may be obtained.

COURTAULDS

Research Chemists

SPONDON, DERBYSHIRE

BRITISH CELANESE LIMITED, part of the COURTAULDS GROUP, have a number of vacancies for Chemists at the Research Laboratories at Spondon, near Derby, which are part of the Courtaulds Research Organisation. These laboratories are concerned with exploratory investigations and process development in the fields of petrochemicals, general organic chemicals, polymers and plastics. Work in these fields covers a diverse range of topics and provides an absorbing challenge for organic or physical chemists.

The Research Laboratories operate a number of pilot plants which can provide valuable experience for anyone wishing to transfer later to production.

Candidates should write for a detailed form of application to the Director of Personnel, Courtaulds Limited, 16 St. Martin's-le-Grand, London, E.C.1, quoting reference number D.12/3.

BOC

SCIENTIFIC DIVISION

A few vacancies occur for:

PHYSICISTS

to investigate high and low temperature processes.

PHYSICAL CHEMISTS

for research in paints, plastics, and low temperature fields.

CHEMICAL ENGINEERS

to undertake low temperature studies concerned with the production and applications of atmospheric gases.

MECHANICAL ENGINEERS

to study low temperature plants and to design pilot plants.

Applicants should have a good honours degree or equivalent and are requested to write to:

The Administration Manager, Scientific Division
THE BRITISH OXYGEN COMPANY LIMITED
Deer Park Road, London, S.W.19

UNIVERSITY COLLEGE OF WALES

WELSH PLANT BREEDING STATION
PLAS GOGERDDAN, NEAR ABERYSTWYTH

Applications are invited for appointment to a vacancy in the Experimental Officer Grade at the Station. The vacancy is in the Cereal and Brassica Breeding Section, and the work is concerned primarily with recording and handling of breeding and genetical material. Applicants should be graduates in agriculture, botany, or agricultural botany. The commencing salary will be determined according to the age and experience of the successful applicant.

Applications, in writing, with the names of two referees, should be sent to the Secretary before August 10.

RESEARCH ASSOCIATION OF BRITISH FLOUR-MILLERS

Applications are invited for the following two posts: 1. Chemist with some research experience in physical or biochemistry to work on certain aspects of the chemistry of wheat protein. Commencing salary between £1,200 and £1,500 with membership of F.S.S.U. 2. Assistant (male) for small animal unit concerned mainly with nutritional research on flour and bread. Must have had some experience in the management of laboratory animals. Salary dependent on age and experience.

Applications, with details of qualifications, etc., to be sent to: The Director of Research, Cereals Research Station, Old London Road, St. Albans, Herts.

AUSTRALIA

THE UNIVERSITY OF NEW SOUTH WALES
CHAIR OF HOSPITAL ADMINISTRATION

The University of New South Wales invites applications for appointment to the Chair of Hospital Administration. The successful applicant will be responsible for the administration and development of the School of Hospital Administration and all courses provided by it, including those of its Department of External Studies. The School provides a course leading to the degree of Master of Hospital Administration and a full-time extension course in Hospital Administration. The Professor will be expected to collaborate in the work of the Faculty and serve on the Professorial Board and other committees. The salary will be £A.4,292 per annum. After passing a medical examination, the successful applicant will be eligible to join the State superannuation scheme, which provides for a maximum pension of £A.2,184 per annum. Professors are eligible for six months' study leave on full salary after three years of service or twelve months after six years of service. Subject to the consent of the Council of the University, Professors may engage in a limited amount of higher consultative work. With the approval of the University and its bankers, married men may be assisted by loans to purchase a home. First-class ship fares to Sydney of appointee and his family will be paid. The University reserves the right to fill the Chair by invitation.

Further details of conditions of appointment may be obtained from the Agent-General for New South Wales from the address given below. Four copies of applications, with the names of three referees and a recent photograph, should be lodged with the Agent-General for New South Wales, 56-57 Strand, London, W.C.2, and a copy forwarded to the Appointments Section, the University of New South Wales, Box 1, Post Office, Kensington, N.S.W., by airmail to arrive before September 8, 1961.

UNIVERSITY COLLEGE OF THE WEST INDIES

Applications are invited for (a) Lectureship or (b) Assistant Lectureship in Chemistry. Applicants should have special interest in Physical Chemistry. Salary scales: (a) £1,050 by £50 to £1,400 by £75 to £1,850 per annum; (b) £800 by £50 to £950 per annum, plus local allowance of £250 per annum (pensionable). Entry according to qualifications and experience, but in case of Assistant Lecturers and Lecturers below merit bar consideration is given to age in fixing salary. F.S.S.U. Child allowance. Settling-in allowance. Unfurnished accommodation at rental of 10 per cent of basic salary. Up to five full passages on appointment, normal termination, and triennial study leave.

Detailed applications (six copies), naming three referees, by August 14, 1961, to Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1, from whom further particulars may be obtained.

RESEARCH FELLOWSHIPS

Vacancies exist for Research Fellows to work on the Tandem Van de Graaff generator, at A.W.R.E., Aldermaston.

The programme currently includes studies of charged particle reactions using proton, deuteron and triton beams with energies up to 14.5 MeV, heavy ion Coulomb excitation using 45 MeV oxygen ions and measurements of nuclear lifetimes. Plans for the installation of a pulsed injector of novel design to enable the Tandem generator to be used for neutron time of flight experiments are at an advanced stage.

Candidates for Research Fellowships must offer proof of their ability to carry out original research in Nuclear Physics and would normally be expected to be in possession of a Ph.D. degree.

Please write for further details to the Senior Recruitment Officer, A.W.R.E., U.K.A.E.A., Aldermaston, Berks, quoting ref. 2974/34.

MSL *have been retained to advise on this appointment.*

DIVISIONAL MANAGER High Vacuum

to create, within a major engineering group, a new team to work on the design and development of rotary and diffusion pumps with associated pipework and gauges for use in mass production processes and research work in scientific, mechanical and engineering fields.

He will be given assistance in staffing his design, drawing office, administrative and commercial department and all production facilities are already available.

Candidates must be graduate physicists or engineers, or hold equivalent institution membership (minimum A.Inst.P. or A.M.I.Mech.E.), with experience of leading a professional team in the design of high vacuum equipment. Administrative and commercial experience is very desirable.

Preferred age 35 to 40. Initial salary not less than £2,000 with pension and life insurance. Please send brief details in confidence to J. G. Smith quoting reference U.9217.

In no circumstances will a candidate's identity be disclosed to our client unless he gives permission after a confidential interview at which he will be given full details of the appointment.

MANAGEMENT SELECTION LIMITED
17 Stratton Street, London, W.1

UNIVERSITY OF LONDON
READERSHIP IN ELECTRICAL ENGINEERING AT IMPERIAL COLLEGE

The Senate invite applications for the Readership in Electrical Engineering with special interest in the properties of materials tenable at Imperial College. Candidates should be capable of initiating and guiding research into the properties of materials such as are related to future developments in electrical engineering. A large well equipped new laboratory will shortly be available. Salary scale £1,675 to £1,975 to £2,425 a year plus £80 London allowance.

Applications (ten copies), must be received not later than August 31, 1961, by the Academic Registrar, University of London, Senate House, W.C.1, from whom further particulars may be obtained.

UNIVERSITY OF MANCHESTER
LINEAR ACCELERATOR PROGRAMME

Short-term appointments are available in the Department of Physics of the Faculty of Science for qualified Physicists or Electrical Engineers to assist with the construction and commissioning of a large heavy ion linear accelerator. Experience in one or more of the following fields would be desirable: high vacuum; R.F. techniques (75 Mc./s.); high power rectifier and pulse circuits; general electronic instrumentation and controls. The appointments are for one year in the first instance, and the salary range is £1,000 to £1,500 per annum.

Applications should be addressed to the Assistant Director, Linear Accelerator Laboratory, Physics Department, the University, Manchester 13, from whom further details may be obtained.

Central Electricity Generating Board

PHYSICS DIVISION

BERKELEY NUCLEAR LABORATORIES (GLOUCESTERSHIRE)

Applications are invited for posts in these Laboratories. Those appointed will work initially in the following sections, although subsequent transfer between sections will be possible, depending on the developing interests and abilities of the staff concerned.

A. INSTRUMENTATION

For work developing nuclear radiation detectors and other specialized nuclear instruments. Preference will be given to candidates who are capable of devising and developing new techniques of measurement.

B. GRAPHITE

To study the fundamental mechanisms and assess the extent of irradiation damage in graphite and the corresponding changes of physical properties.

C. THEORETICAL PHYSICS

To study various theoretical problems of interest to the Laboratories, including reactor physics and the theory of radiation damage.

- **Initial salaries up to £1,325 per annum are offered in accordance with experience, ability, and qualifications of persons appointed.**

Candidates must have a good honours degree and should be under 26 years of age.

Applications, stating age, qualifications, experience, present position, salary and quoting type of work interested in, to the Appointments Officer, 24/30 Holborn, London, E.C.1, by August 3. Quote Ref. N/317.

R.N. COLLEGE, GREENWICH, LONDON, S.E.10. Post for Senior Lecturer or Lecturer in Physics and Electrical Engineering available January, 1962. Candidates (male) must be British and possess an appropriate honours degree. Duties include lecturing and conducting laboratory work to degree standard and postgraduate teaching. Special experience in telecommunications an advantage. Excellent research facilities. Appointment as Senior Lecturer (£1,392 to £1,714) or Lecturer £773 to £1,267) according to age, qualifications and experience. Starting salary above minimum may be authorized. Post carries F.S.S.U. benefits. Single accommodation available.—Particulars and application forms from Director (P), Education Department, Admiralty, London, S.W.1. Closing date for applications August 31, 1961.

AUSTRALIAN NATIONAL UNIVERSITY

JOHN CURTIN SCHOOL OF MEDICAL RESEARCH

DEPARTMENT OF BIOCHEMISTRY

Applications are invited for a Readership and a Fellowship in the Department of Biochemistry (Head of Department: Professor A. H. Ennor, D.Sc., F.A.A.). The Department is well equipped to carry out studies involving protein fractionation, enzyme purification, and most aspects of associated biochemical work. It is also provided with modern counting equipment for use with tritium, C^{14} and other radioactive isotopes. Applicants for the Readership will be expected to have had extensive experience in biochemistry with emphasis on enzymology and intermediary metabolism. They will also be expected to have made substantial published contributions to the subject. The salary range for a Reader is £A.3,250 to £A.3,750 per annum, and the successful applicant will be made a permanent member of the University staff. A Reader is entitled to one year's study leave on full pay, plus a contribution towards travel and other expenses, in every six years. Applicants for the Fellowship will be expected to have had considerable experience in enzymology or in intermediary metabolism. The salary range for a Fellow is determined within the limits £A.2,120 to £A.3,000 per annum. Appointment is for an initial period of five years and thereafter may be made permanent. A Fellow is entitled to one year's study leave on full pay, plus a contribution towards travel and other expenses, in every seven years. In both cases commencing salary will depend on qualifications and experience. Superannuation is on the F.S.S.U. pattern. Reasonable travel expenses are paid and assistance with housing is provided.

Further details should be obtained from the Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1. Applications close, in Australia and London, on September 1, 1961.

AUSTRALIAN NATIONAL UNIVERSITY

JOHN CURTIN SCHOOL OF MEDICAL RESEARCH

DEPARTMENT OF PHYSIOLOGY

Applications are invited for a Fellowship in the Department of Physiology. Applicants will be expected to have specialized in organic chemistry, with special reference to the chemistry of compounds of neuropharmacological significance. The salary range for a Fellow is determined within the limits £A.2,120 to £A.3,000. Appointment is for an initial period of five years and thereafter may be made permanent. A Fellow is entitled to one year's study leave on full pay, plus a contribution towards travel and other expenses, in every seven years. The commencing salary will depend on qualifications and experience. Superannuation is on the F.S.S.U. pattern. Reasonable travel expenses are paid and assistance with housing is provided.

Further details should be obtained from the Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1. Applications close, in Australia and London, on August 14, 1961.

UNIVERSITY OF ADELAIDE

WAITE AGRICULTURAL RESEARCH INSTITUTE

The University invites applications for appointment at the Waite Institute as Lecturer in Crop Ecology. Duties: To undertake ecological or physiological studies on the lucerne crop, and to evaluate and develop lucerne ecotypes for grazing. The appointment is financed by a grant from the Wool Research Trust Fund and will be made within the Lecturer salary range of £A.1,675 by A.95 to £A.2,340, with provision for superannuation on the F.S.S.U. basis. The appointment is for three years in the first instance, renewable annually thereafter. The Waite Institute has excellent facilities in field, glasshouse, and laboratory, and the lecturer will be associated with a considerable group of colleagues in his own field of study.

Further information about the University and this appointment and the general conditions of appointment can be obtained from the Registrar of the University or the Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1. Applications, in duplicate, setting out the information specified in the last paragraph of the general conditions, should be lodged with the Registrar, The University of Adelaide, Adelaide, South Australia, not later than August 31, 1961.

A SENIOR PHARMACOLOGIST

To be in charge of the Pharmacology Laboratories which are at present in the course of construction for Reckitt and Sons Ltd.

This Company is a member of the Reckitt and Colman Holdings Group, which has considerable interests in pharmaceutical, foodstuff, household, cosmetic, horticultural and other product groups in Britain and in over 25 countries overseas.

The headquarters of pharmaceutical research and development are in Hull, where the existing Laboratories are being extended to provide new Laboratories for research in pharmacology, biochemistry, pathology and histology.

The Organic Chemistry Laboratory is already established and well-equipped to support the new Pharmacology Laboratory in research directed to the development of medicinal chemicals.

There is a good Library and Information Service and a Statistical Department is available for help in the planning and analysis of experimental work.

The Senior Pharmacologist should have some years' post-doctoral experience, either in an academic institution or in an industrial establishment, and will be encouraged to pursue special research interests. The conditions of work and employment are excellent and the attitude towards research is liberal.

The salary paid will be a matter for individual discussion. There is a good contributory pension fund with provision for widows and dependants, and a Prosperity Sharing Scheme. Assistance will be given in securing housing accommodation.

Inquiries will be treated in strict confidence and should be addressed to the Technical Director, Reckitt and Sons Ltd., Dansom Lane, Hull.

AUSTRALIAN ATOMIC ENERGY COMMISSION

RESEARCH ESTABLISHMENT

REACTOR PHYSICS

Applications are invited for the following senior positions in the Reactor Physics Section at the Research Establishment, Lucas Heights, N.S.W.

Grade: Senior or Principal Research Officer.

Salary: £2,395/£2,720 or £2,980/£3,500 (Aust.).

Duties: (Position R.18.) To take charge of a group working on sub-critical and critical reactor problems and experiments associated with the AAEC high temperature gas-cooled reactor programme. Major equipment includes HIFAR, the 10 MW DIDO-class reactor and MOATA, the 10 KW UTR-10 type reactor.

Duties: (Position R.80.) To carry out neutron physics studies both of a fundamental nature and also associated with the AAEC high temperature gas-cooled reactor programme, particularly neutron energy spectrum, spectrum, conversion ratio and resonance integral measurements, and general neutron reaction studies over a wide energy range.

Qualifications: Honours or Higher Degree in Physics and several years' relevant experience.

Travel: Under specified conditions, first-class air/sea transport for the appointee and dependants (wife and dependent children) will be provided.

Contract Employment: Consideration may be given to a contract agreement if the appointee desires to enter into an agreement for a three (3) year contract of employment in Australia. In this case, the AAEC will bear the cost of the return fares together with assistance for removing the appointee's furniture and effects.

Applications: Forms obtainable from AAEC Liaison Officer, Australia House, Strand, London, W.C.2. OTHER POSITIONS are vacant in these groups in the Research and Senior Research Officer range £1,510 to £2,265 and £2,395 to £2,720 (Aust.). Enquiries to the above address.

PATHOLOGICAL LABORATORY TECHNICIAN

Applications are invited for the position of Pathological Laboratory Technician with a well-known firm of pet food manufacturers.

The successful applicant should be a member of the Institute of Medical Laboratory Technicians, and have passed the intermediate examination of the Institute. Experience should include all branches of this field including Histology.

Starting salary will not be less than £950, rising to a maximum of £1,400 per annum.

In addition the company operates generous non-contributory pension, sickness and life assurance schemes.

Write for an application form giving brief details to the:

Personnel Officer (S),
PETFOODS LIMITED
Melton Mowbray, Leics.

UNIVERSITY OF QUEENSLAND

LECTURER IN MECHANICAL ENGINEERING

The University invites applications for the above-mentioned position. Applicants should possess a Degree, preferably with Honours, in Mechanical Engineering of a recognized university. Some industrial experience is highly desirable. Previous teaching experience, although desirable, is not absolutely essential. The appointee will be required to conduct lectures, laboratory and drawing office work in the fields of Applied Mechanics (including dynamics and stress analysis) and Engineering Drawing and Design. Salary £A.1,830 by £A.70 to £A.2,330 per annum. The Department has a very active research and postgraduate school and has already achieved world standing for its research into the mechanical milling of sugar cane and the application of solar energy to air-conditioning. It possesses well equipped laboratories, including a machine tool laboratory and workshop capable of precision work, and an excellent Metrology Laboratory which is registered by the Australian National Association of Testing Authorities. The successful applicant will be entitled to participate in the benefits available to the academic staff which include F.S.S.U. type superannuation, housing assistance, study leave, and travel grants.

Additional information on the conditions of appointment, staffing, and activities of the Department, together with application forms, will be supplied on request to the Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1. Applications close, in Australia and London, on August 31, 1961.

HUDDERSFIELD COLLEGE OF TECHNOLOGY

Principal: Dr. W. E. Scott, M.B.E.

DEPARTMENT OF PHYSICS

Required September 1, 1961, or earlier if possible, Grade B Assistant to teach Physics. Salary (Burnham Scale) £700 by £27 10s. to £1,150 per annum. There are additions for approved qualifications and training, and the commencing salary may include increments for approved industrial experience.

Forms of application and further particulars obtainable from the Principal, to whom applications should be returned without delay.

H. GRAY,
Clerk to the Governors.

BACTERIOLOGICAL TECHNICIAN

A technician aged 20 upwards is required in the Heinz Bacteriological Laboratory where he will be engaged primarily on heat sterilisation problems.

This opening would be suitable to a young man who has achieved one of the following qualifications:

Intermediate I.M.L.T.
Endorsed Certificate (Inst. of Biol.).
Membership I.S.T.

but practical experience in Bacteriology is the most important consideration.

Conditions of employment are excellent and include a non-contributory pension and life assurance.

Further study is actively encouraged by the Company and an excellent Tuition Aid Scheme is in operation.

Please apply with a brief summary of personal history to date to:

The Personnel Officer,
H. J. Heinz Company Limited,
Waxlow Road, Harlesden,
London, N.W.10.

RESEARCH CHEMIST REQUIRED BY A large London Brewery. Applicants should have a first-class honours degree. Industrial experience not necessary. Interesting work and good remuneration.—Please write, giving full details of education and qualifications, to Box 978, T. G. Scott and Son, Ltd., 1 Clement's Inn, London, W.C.2.

INSTITUTE OF CANCER RESEARCH: Royal Cancer Hospital. Technical Assistant required in Chemical Section of laboratory engaged in radiobiological research at Sutton, Surrey. Varied work involving a wide range of chemical and physical techniques. Salary on M.R.C. scales within range £370 to £860 according to age, qualifications and experience.—Applications, with names of two referees, to the Secretary, 33 Sumner Place, S.W.7, quoting ref. 301/B/59.

UNIVERSITY OF CAPE TOWN

SENIOR LECTURER OR LECTURER IN ZOOLOGY

Applications are invited for the above-mentioned post. The duties attaching to the post will include teaching and laboratory supervision of students and some examining and organizing of courses. The successful applicant will also be expected to undertake research work. A thorough knowledge of Comparative and General Physiology is essential. The appointment will be made at the Lecturer or Senior Lecturer grade according to qualifications and experience. The Senior Lecturer will be required to take charge of degree courses in General Physiology and to give instruction in Comparative Animal Physiology for advanced students in zoology. The lecturer will be required to perform similar duties but will not be in charge of the teaching in General Physiology. The salary scale is R.3,520 by R.120 to R.4.120 (£1,760 by £60 to £2,060) per annum for a Senior Lecturer and R.2,680 by R.120 to R.3,520 (£1,340 by £60 to £1,760) per annum for a Lecturer. Applicants should state age, experience, academic qualifications, research work completed or in progress, and give the names of two referees whom the University may consult.

Two copies of the application and testimonials should reach the Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (from whom memoranda giving the general conditions of appointment, including transport expenses on appointment, and information on the work of the department may be obtained) not later than August 21, 1961. An additional copy should be sent direct by airmail to the Registrar, University of Cape Town, Private Bag, Rondebosch, Cape Town, South Africa, to reach him by the same date. The University reserves the right to appoint a person other than one of the applicants or to make no appointment.

UNIVERSITY OF KHARTOUM

Applications are invited for the appointment of two Senior Technicians or Technicians in the Faculty of Veterinary Science: 1. In the Department of Animal Health. 2. In the Pre-Clinical Department. Minimum qualification Certificate of Membership of the Institute of Laboratory Technicians (M.I.L.T.) or its equivalent, plus for the first post, at least five years experience in bacteriological techniques in a recognized veterinary or medical institution; and for the second post, at least five years experience in various techniques of histological preparations and anatomical museum specimens. Salary scales: Senior Technician, £S.1,250 by £S.50 to £S.1,500 per annum; Technician, £S.950 by £S.50 to £S.1,200 per annum. Entry point according to qualifications and experience. Generous allowances are payable. Passages for appointee and family on appoinment, termination and annual leave. There is a superannuation scheme and arrangements can be made to maintain F.S.S.U. policies. Appointment on contract for five years with possibility of renewal. Unfurnished accommodation provided at rent (excluding rates) up to 7½ per cent of salary.

Applications (six copies), detailing qualifications and experience and naming three referees by August 18, 1961, to Registrar, University of Khartoum, c/o Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1, from whom further particulars may be obtained.

UNIVERSITY OF ST. ANDREWS

Applications are invited for the posts of Research Assistant and Research Student in the Wellcome Laboratories of Pharmacology, Gatty Marine Laboratory, St. Andrews. Candidates should be suitably qualified in zoology, physiology, biochemistry or chemistry, for work on the endocrinology of lower vertebrates. Suitable candidates may register for a higher degree. Salary scale for Research Assistant £700 to £800; for Research Student £400 to £500; appointment for three years in the first instance.

Applications, with names of three referees, should be lodged, not later than July 31, 1961, with the Joint Clerk to the University Court, College Gate, St. Andrews.

APPLICATIONS ARE INVITED FOR A post as Research Assistant to take part in a programme designed to study human chromosome abnormalities and associated disorders. Experience in cytology desirable, but not essential. Suitable for candidates graduating this year. There may be opportunity to read for a higher degree. Salary £700 to £900 per annum, according to qualifications and experience.—For further details please apply to the Secretary, Genetics Department, the University, Sheffield, 10.

CONSERVATION OF WATER IN GREAT BRITAIN

WATER has been the key to man's advancement since before the beginning of recorded history. Not only do we need it for personal use, but it is also essential to grow crops, to water stock, to move cargoes, and to dispose of wastes. Many manufacturing processes depend on this precious liquid: it is the universal solvent, the universal coolant. It powers part of industry, and when work is done it is essential to much recreational activity. Without water, life as we know it would cease. To-day, this vital raw material is assuming an ever-increasing importance as the need for it and water-related services and products grow. Inconvenience arises by both an absence or over-abundance of water. The conservation of water therefore becomes of importance whenever extremes are experienced, or when the demand for water by a growing community begins to exceed the minimum supply available. There has been for some years now mounting evidence that we are rapidly approaching a time when the latter situation will arise in Great Britain.

In 1959, as a result of a dry summer, some ten million people (nearly one quarter of the population of England and Wales) were affected by drought orders or restrictions on their water supply. Moreover, although 1959 had a remarkably dry summer the year as a whole was not exceptionally dry—there have been ten drier years in the present century, notably in 1955. These restrictions demonstrated the already known fact that Great Britain's defences against drought have been a diminishing quantity for some time[1]. On the other hand, the above-average rainfall in the autumn of 1960, coming after a wet summer, led to very serious and prolonged flooding in a number of areas. These experiences now seem to have convinced the central Government authorities that there is an increasing need to regard water as a prime natural resource basic to our existence, and to legislate for its conservation and proper use.

The past year or so has seen the welcome appearance of a number of valuable reports and publications, notably the hydrological surveys and the annual year books issued by the Surface Water Survey[2], together with the reports of the Central Advisory Water Committee[3] and the Welsh Advisory Water Committee[4]. The British National Committee for Geodesy and Geophysics has also issued a useful report on current hydrological activity in the United Kingdom[5].

Valuable as these reports are, it must be admitted that they do not match up to the remarkable study of the same problem undertaken in the United States during the past two years by the Senate Select Committee on National Water Resources[6]. The British reports, however, represent a significant step in the right direction, and accompanying them have been welcome indications that the Ministry of Housing and Local Government is now preparing the way for new legislation to meet the future water needs of the country. In June 1960 the Minister stated: "We are approaching the point at which we may very possibly have to take a new look at water conservation. . . . It may be that the time is not far distant when we have to look at all the resources of a river basin as a whole in the widest possible way, to make sure that all the various and sometimes conflicting interests are properly served; that the river is kept clean and the interests of fishing, navigation and so on are safeguarded, while, at the same time, the maximum amount of water is made available to all kinds of users as economically as possible".

Since this announcement, one of the sub-committees of the Central Advisory Water Committee has made an investigation into the complex problems involved in achieving this end, and the Committee is now engaged on the preparation of a report. In view of the public concern and of the wide support that can be expected for a bold approach, the Minister has decided to open confidential discussions with representatives of affected interests, both private and public, in advance of the report. An indication has therefore recently been given by the Ministry of the proposals which it has in mind as a basis for legislation dealing with water conservation.

There has been support in some quarters for a Central Water Authority mainly concerned with policy and planning, but also possessing powers of direction. It has been suggested that such an authority should have a regional organization with executive powers, and ideas on its constitution have varied from a body such as the Central Advisory Water Committee with extended functions, to a newly appointed permanent body of persons with specialist experience and knowledge in water problems. This proposition has been considered, but has been rejected by the Minister on grounds of constitutional and administrative difficulties.

It is proposed instead to set up conservation authorities and to re-define the powers and responsibilities of the Minister. Section 1 of the Water Act, 1945, requires the Minister "to promote the conservation and proper use of water resources and the provision of water supplies in England and Wales and to secure the effective execution by water undertakers under his control and direction, of a national policy relating to water". The present statutory provisions, however, are ill-suited for the execution of this policy: thus the only specific provision to enable conservation to be carried out is to be found in section 14 of the Act, which empowers the Minister to control new abstractions of underground water in those parts of the country designated as conservation areas. So far as surface water is concerned, there is no provision whereby both the development and allocation of supplies can be controlled in the light of an overall plan which has regard to all the various interests involved. It has been clear to many and for some time now that if we are to make the best use of our water resources and due regard is to be paid to future needs, then a completely new comprehensive approach is urgently needed.

The Minister has accepted that any new approach should be based on certain propositions which are beyond argument. These are briefly: (*a*) that the approach to the problem should be by way of the natural hydrological unit of the river basin; (*b*) that surface and underground water are interdependent and any measures for development and control must be related to both; (*c*) that the machinery of conservation must be capable of taking into account all the conflicting interests; (*d*) that regulatory powers alone are insufficient and that a positive policy involving new works will in certain cases be necessary; (*e*) that a need will exist for some central co-ordinating and appellate authority.

It is therefore proposed to establish water conservation authorities (their exact title has yet to be decided) founded on river basins or groups of river basins. The question immediately arises whether the new organizations should be set up in parallel with the existing river boards. In the Minister's view, conservation functions and those at present carried out by river boards are so interdependent that they should be the responsibility of a single authority in each area.

It is thought that the new conservation authorities should be responsible for: (*a*) keeping a complete up-to-date hydrological survey of the area; (*b*) the preparation of an overall plan for the development of the water resources; (*c*) the control and development of the resources; (*d*) the allocation of water between users by means of a licensing system, subject to a right of appeal to the central authority; (*e*) the recharge of underground aquifers, the discharge of compensation water and the transfer of water between conservation areas; (*f*) land drainage, flood prevention and the control of pollution; (*g*) the administration of salmon and freshwater fisheries legislation, and the reconciliation of navigational needs with the above interests.

The new approach is therefore comprehensive, and all water-using interests in a particular river basin would be brought under the one umbrella of the conservation authority. This is, in fact, the logical pattern which has been and is being followed in the development of many new overseas territories. The existing system within England and Wales has grown up piecemeal over the centuries, and we now have a great multiplicity of bodies concerned with all the above aspects, and the boundaries of which rarely reflect the basic hydrological and geographical facts. The transformation will clearly not be achieved without some opposition and will take some time. It is important, however, that progress on these lines should be made in order to ensure adequate supplies of water for future generations.

The financial aspects of the proposals are likely to be complex and will need careful thought. It is proposed to hold discussions with affected interests before any final report is issued. The principle that the cost of the main land-drainage system of an area should be financed by the community it serves has long been established and is not changed by the proposals of the Land Drainage Bill at present before Parliament. Therefore, as land-drainage authorities it is thought that the new conservation bodies should inherit from the river boards those boards' sources of income, that is, precepts on local authorities and on internal drainage boards, the proposed general and special drainage charges and the Exchequer grants payable to the boards at the present time.

As conservation authorities, expenditure would be incurred on administration and control, research, and on the building and maintenance of a variety of works to ensure the best use of the water resources. It is thought that this expenditure should be self-supporting on the basis of income received from water users within the area. The exact method by which this income would be raised has yet to be decided: licence fees, consumption charges, flat rates, etc., will be fully considered. There is, however, likely to be a special feature in the early years in that some major works will be desirable well in advance of the maximum demands which are likely to arise. Present-day users cannot always be expected to meet the full cost of works which will serve the interests of the new generation, and the Minister proposes that authorities should be empowered to levy a small precept (possibly not more than the product of a 1*d*. rate) for conservation works. In time it is thought that the water conservation authorities would be able to accumulate reserves against forthcoming capital expenditure and that the need for precepts would become less.

The financial suggestions are somewhat less definite than the hydrological proposals, and one can foresee a good deal of difficulty arising because of the inequality in the distribution of water resources, population and other economic resources. The intention not to seek powers to make Exchequer grants towards expenditure might well prove to be a pious hope. Some schemes are likely to be beyond the financial capabilities of the parent river basin and if completed might benefit larger areas. It would be desirable to consider the country as a whole as well as the individual parts. Clearly, much discussion and thought will be needed before the financial aspects are presented to Parliament.

The constitution of the water conservation authorities will also need careful thought. The principle underlying the constitution of the river boards is that those interests contributing to their revenues should be represented on them. This principle applied to the proposed conservation authorities would produce a large and unwieldy body. An alternative would be a small nominated group appointed by the Minister in consultation with the interests concerned. There is a constitutional difficulty here in that, apart from the Metropolitan Police, nominated bodies have not the power to precept. However, the water conservation authorities will themselves be unprecedented, and it may be that the interests concerned would be prepared to accept a nominated body. Another alternative would be a body half elected and half nominated: here the

Milford Haven Conservancy Act of 1958 might provide a guide.

It will be clear that some of the Minister's existing functions under the 1945 Act would with the above proposals pass to the water conservation authorities. The Minister's powers and responsibilities with regard to conservation would need re-defining in order to cover the co-ordination of the conservation authorities' assessments of local resources and potentialities; to watch from the national point of view the demand for water for domestic, industrial, agricultural and other purposes; to approve conservation schemes; to authorize and initiate schemes for inter-basin transference of water; to exercise appellate functions arising from decisions of the conservation authorities; and to approve capital investment programmes of the conservation authorities.

A new approach will also be necessary on the legal rights to particular water resources. Parliament has already considered it proper to restrict in some cases the right, arising from ownership of land, to take the water from beneath the land. It is further intended to amend the law so as to restrict the amount of water which can be taken without licence from boreholes sunk before control was applied, as well as to extend control to all underground waters. In the case of right to surface water, more particularly the rights of a riparian owner to use water flowing in a stream, it is proposed to provide that such an owner will be able to obtain as a right, from the conservation authority, a licence entitling him to the ordinary use of the water flowing past his land. "Ordinary" use will not include abstraction for irrigation and industrial purposes, and these uses will involve separate licences.

With water-storage capacity in Britain falling steadily behind rising consumption-rates, insurance against drought diminishes year by year and the need for both action and speed is pressing. The proposals outlined above are a welcome indication that the central Government authorities are at last alive to the necessity for comprehensive measures.

ACHIEVEMENTS IN PHYSICS

The New Age in Physics

By Prof. Sir Harrie Massey. Pp. 342+12 plates. (London: Elek Books, Ltd., 1960.) 42*s*. net.

ABOUT thirty years ago, physical science seemed to many of its students to have reached a peak of perfection. The nuclear atom held an established position and the power of quantum theory in interpreting atomic phenomena had been abundantly confirmed. Observational astronomy and thermodynamics had combined to predict the probable fate of the Sun and stars; only details apparently remained to be fitted into what was considered to be an elegant and satisfactory picture of the physical universe. One of the marks of this stage of achievement was the appearance of books of broad coverage, notably those of Jeans and Eddington, which sought to stimulate the interest of the general reader in the processes of scientific thought and experiment. The significance of these books was not diminished by the fact that the apparent self-sufficiency of physics in 1930 rapidly proved to be illusory. The spectacular discoveries in nuclear physics in the following decade became, as a result of awakening interest, increasingly matters of public concern.

By the end of the Second World War, physics was accepted as one of the basic elements of a scientific civilization, and it is now a commonplace that some knowledge of the subject and of its applications in contemporary affairs should form part of general education. Even more than in the days of Jeans and Eddington, there is a need for sober and balanced, but easily readable, works of exposition. It is to this need that Sir Harrie Massey's book makes a notable contribution.

The New Age in Physics is a book for the educated layman, but it can be read with pleasure and profit by the professional physicist. The mathematics used is of the simplest kind, but is sufficient to show that physics is above all a quantitative subject. Most of the book is devoted to atomic, nuclear and high-energy physics, and this is right, since it is on the atomic and nuclear scale that the new laws of physics exhibit their strangest manifestations. Sir Harrie Massey is known to the general public as an enthusiastic supporter of the space research programme, and it is therefore not surprising to find his chapter on neutrino phenomena ending with an account of hydrogen burning in the Sun, and his next (and final) three chapters devoted to radio astronomy, exploring the upper atmosphere, and artificial satellites and space probes. These chapters, like that on fission and fusion, are admirably lucid and compact accounts of the developments in physics which have most deeply excited the popular imagination. They will probably be more fully appreciated by the general reader than the rest of the book, which is concerned as much with concepts as with facts. Few non-scientific readers, however much they enjoy the adventures of Alice in "Looking-Glass House", will really find themselves greatly moved to learn that mirror symmetry is violated in weak interactions. Nor is the polarization of the vacuum a matter of everyday experience, although the ideas of special relativity are being increasingly discussed as interplanetary travel enters more within the bounds of possibility.

In his introduction the author sets out his intention to "choose a number of outstanding theoretical and experimental developments which illustrate the remarkable position which has been reached and the extraordinary rate of progress". In the event, one may comment that little choice has been necessary, since practically everything of general interest in atomic and nuclear physics, in the physics of the solid state, and in that of the solar system receives some mention. It is a pleasure to have authoritative and informative accounts of the contents of such an extensive field, and to sense an underlying unity of treatment which is often lacking in works of similar scope. The book gains much from well-chosen illustrations, and suffers but little from the finite number of misprints and the occasional errors in dates. It has an air of currency, but even so, it has just missed the Mössbauer effect, and it would be entirely consistent with the author's belief in the inexhaustible bounty of Nature if some outstanding event were to occur before the book reached a second edition. Perhaps one may hope that when the stage is set and the space station exists, mankind may be offered the spectacle of another supernova in his own galaxy.

W. E. BURCHAM

A NEW APPROACH TO GENERAL RELATIVITY

Relativity

The General Theory. By J. L. Synge. (Series in Physics.) Pp. xv+505. (Amsterdam: North-Holland Publishing Company; New York: Interscience Publishers, Inc., 1960.) 110*s*.

THIS massive treatise is no mere conventional text-book of Einstein's theory of gravitation. On the contrary, although by a master of that subject, it is a highly individual work. For, although the author claims that the book is conservative in so far as it deals mainly with Einstein's theory in its original form, leading up to the famous triad of empirical tests, the mathematical treatment is novel. This treatment derives from Synge's conviction that, great as was Einstein's achievement, the true revolution in mental perspective was due to Minkowski, although this has not yet been fully appreciated by most students of the subject.

In accordance with a recent tendency among some students of relativity, Synge will have nothing to do with the principle of equivalence. Instead, he maintains that in Einstein's theory the existence of a gravitational field depends entirely on whether or not the curvature tensor does not or does vanish. This is an absolute property of space-time and does not depend on the observer. Synge accordingly endorses Minkowski's protest against the use of the word 'relativity' to describe a theory based on an 'absolute' (space-time). Indeed, he remarks that if Minkowski had lived to see the general theory of relativity he would have repeated his protest in stronger terms.

Although Synge's outlook is geometrical, in the sense that it is based on a thorough-going acceptance of the space-time way of looking at things with its fixed diagrams which are "easier to deal with" than the kinematical pictures of Newtonian mechanics, the peculiarity of his approach lies in combining this point of view with a deep conviction that time is the only basic measure, distance being essentially a derived concept. Consequently, Synge's version of general relativity is based on what he prefers to call Riemannian 'chronometry' rather than 'geometry'. This leads him to make general relativity more 'operational' (in Bridgman's sense) and thus more closely related to special relativity than has previously been customary. In this respect, I believe that Synge has been indirectly influenced by the pioneer example of kinematic relativity.

In considering the geodesic world-line of a particle in free fall, Synge interprets gravitational acceleration as a consequence of the curvature of the world-line of the observer. He is thus led to develop a new method of gravitational analysis based on a function first introduced in 1931 by H. S. Ruse. This function, which Synge calls the 'world-function,' is, to within a trivial factor, the square of the geodesic distance between two events in space-time, regarded as a function of the eight co-ordinates concerned. His use of this function has the advantage of combining the power-series technique with that of the tensor calculus.

Among the many topics discussed are Fermi transport, the material continuum and field equations, integral conservation laws and equations of motion, special universes, gravitational waves and geometrical optics. There is an extensive bibliography with references to reviews. The print is clear and the formal mathematics is relieved from time to time by the author's irony and wit. Irrespective of whether one accepts his point of view, his book will be found original and stimulating.

G. J. WHITROW

NEW HANDBOOKS FOR LUNAR STUDIES

Structure of the Moon's Surface

By Dr. Gilbert Fielder. Pp. xiii+266. (London and New York: Pergamon Press, 1961.) 50*s*. net.

Surface of the Moon

Its Structure and Origin. By V. A. Firsoff. Pp. 128+10 plates. (London: Hutchinson and Co. (Publishers), Ltd., 1961.) 21*s*. net.

Orthographic Atlas of the Moon

Compiled by D. W. G. Arthur and E. A. Whitaker. Edited by Gerard P. Kuiper. Edition "A" showing the Standard Orthographic Coordinate Grid. Part 1: Central Area. (Contributions, Lunar and Planetary Laboratory, No. 1.) Pp. 3+31 plates. (Tucson: University of Arizona Press, 1960.) n.p.

RESEARCH into the nature of the Moon's surface has become increasingly intensive in recent years. This increase can partly be ascribed to the advances in 'space-science', in particular the Russian achievement in photographing the Moon's 'other face'. However, new ideas had begun to appear before this. Spurr's *Geology Applied to Selenogy* was published between 1944 and 1949; although neither Dr. Fielder nor Mr. Firsoff subscribe to Spurr's speculative theories, they both believe that terrestrial geology is of prime importance in interpreting the appearance of the Moon's surface. They also share the view that the morphology of the surface features is a more rewarding line of research than the recording of ever smaller minutiæ.

Dr. Fielder's book is a complete handbook to the Moon. It is divided into two parts: the first describes the methods used to determine the physical properties of the Moon's surface and discusses the available observations. The second part is devoted to the morphology of the lunar surface, where the author's own researches play a more prominent part. Ray systems, the grid system, rilles and wrinkle ridges, and the distribution and frequency of craters are subjects well fitted to this approach. The book concludes with a chapter on the origin of the Moon's surface. This does not support any particular theory but is confined to what may reasonably be inferred from observation. Dr. Fielder has covered his subject completely and thoroughly—the only faults are occasional lapses into irrelevance.

For many years there have been two rival theories for the formation of lunar craters—the meteoric, which explains them as the result of meteors striking the surface, and the volcanic, which identifies them with extinct volcanoes. Mr. Firsoff's book is an exposition of his own theory, which is derived from the latter. The craters are now identified as collapsed volcanic calderas, the result of the collapse of the surface layers after the magma beneath them had been spewed out in a volcanic eruption. The book is divided into three parts of which the first outlines what is known about the Moon. The second examines the inadequacies of the meteoric theory and puts forward the 'caldera' theory. The third is concerned with reducing our present knowledge of the Moon's surface to a coherent system; it is largely devoted to an examination of the analogies between the surfaces of the Moon and Earth. The chief criticism to be levelled at this clear and closely reasoned book is the reckless use of the word 'random'. In a scientific work this word should be confined to its statistical sense.

In 1960 a team of workers led by G. P. Kuiper published their *Photographic Lunar Atlas*. This covered every part of the Moon's surface four times, at differing angles of illumination, on a scale of one millimetre to every 1·37 km. on the Moon. The group have now published the first of a series of supplements. Twenty-nine of the best prints in the *Atlas* have been chosen to give a single coverage of the central portion of the Moon's disk. These are over-printed with a grid showing the orthographic ξ,η co-ordinates, in other words, rectangular co-ordinates fixed in the Moon with ξ axis northwards and ζ axis towards the Earth. The side of each square is 0·01 of the Moon's radius and positions can easily be read to an accuracy of 0·001. There are two editions: (*A*), on paper as described above and (*B*), on 'Tensalex' plastic, with an additional grid showing selenocentric longitude and latitude at 2° intervals.

D. H. P. JONES

ISSUES IN EVOLUTION

Evolution after Darwin

Edited by Sol Tax and Charles Callender. Vol. 3: Issues in Evolution. Pp. viii + 310. (Chicago: University of Chicago Press; London: Cambridge University Press, 1960.) 60*s*. net.

THIS is the third volume of the Darwinian Centennial Symposium held at Chicago in 1959 (see *Nature*, 189, 340; 1961 for review of previous volumes). It comprises a first section on "Evolution and Religion" presented as essays on "Creation and Evolution in the Far East" by Ilza Veith, "Current Roman Catholic Thought on Evolution" by J. Franklin Ewing, *S. J.*, and "Creation and Causality in the History of Christian Thought" by Jaroslav Pelikan (it is refreshing to note that a Roman Catholic view has been included). The second section is given over to the centennial celebrations, made up chiefly of a television preview panel of five scientists and including Adlai Stevenson, five panels on the origin of life, the evolution of life, man as an organism, the evolution of mind, and social and cultural evolution, with a variety of chairmen and panellists. There is a convocation address by Sir Julian Huxley, a final television postscript panel and a personal conclusion by the general editor, Sol Tax. The index to the three volumes is included in this third volume, and there are also lists and photographs of the participants and panels.

The five panels were essentially a form of glorified 'brains trust' on a high level, and they were all given in public to audiences of about a thousand people. Members of the panels for the most part were generally those who had previously given papers in the first two volumes of this series. Thus the opportunity was given to tie up loose ends, to give the participants a chance to air their agreements and disagreements, and to put forward their ideas. These panels were most interesting, and probably their chief result will be to enable readers of the whole series of essays to sort out facts from speculations and to assess the present state of evolutionary ideas.

It is perhaps significant that the three essays on "Evolution and Religion" together amounted to only 40 pages, less than half the number of pages of some of the essays on specialized topics in the first two volumes. About 90 pages were given to such subjects as the "Origin of Life"—a subject which surely by any serious standard is about 99 per cent speculation and fancy and only 1 per cent fact. The contrast here is illuminating, but, dare I say it without fear of excommunication by my fellow biologists, it also pinpoints the paucity of evolutionary theory as a whole in spite of the brilliant expositions of its magnificent edifice by so many scientists; it also shows the weakness and barrenness of a purely materialistic concept of evolution and indicates without doubt that modern evolutionary theory has only a limited application to human beings. Why must biologists shut their eyes to the spiritual in man, pretend it is not there and thus remain only on the fringes of the study of the nature of man, who is demonstrably infinitely more than a mere animal? It is a tragedy that a wonderful chance to produce a modern synthesis of knowledge of man and evolution has been missed in this great and superbly produced series of books born of a great idea by Sol Tax. But still the three books as a whole stand as probably the best of their kind so far published, and the committee under Sol Tax, the contributors and the University of Chicago, which made it possible, are to be congratulated and thanked.

P. G. FOTHERGILL

HETEROCYCLIC CHEMISTRY

Pyridine and Its Derivatives

Edited by Erwin Klingsberg. (The Chemistry of Heterocyclic Compounds: a Series of Monographs, Vol. 14). Part 1. Pp. x + 613. 367*s*. Part 2. Pp. x + 576. 282*s*. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1960 and 1961.)

Heterocyclic Systems with Bridgehead Nitrogen Atoms

Part 1. By William L. Mosby. (The Chemistry of Heterocyclic Compounds: a Series of Monographs, Vol. 15). Pp. viii + 747. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1961.) 360*s*.

WITH two or three exceptions, previous volumes in the Interscience Series, *The Chemistry of Heterocyclic Compounds*, have tended to dwell on the less common heterocyclic systems. This is true of only one of the three volumes under review, and it is interesting to see the treatment accorded to a more familiar topic—*Pyridine and its Derivatives*. The first two volumes discussed here constitute Parts 1 and 2 of a four-volume treatise, which will surely become the standard reference work on pyridine chemistry and a worthy successor to Maier-Bode's *Das Pyridin*.

Volume 1 comprises two chapters, the first of which is devoted to an introductory account of the physical properties and chemical reactions of pyridine and its simple derivatives. This is, in itself, a useful 90-page summary of pyridine chemistry and the author has made an admirable job of correlating and unifying the subject in terms of electronic theory. He has also provided an appropriate introduction to the remaining volumes of the treatise which deal, in detail, with a number of specialized topics. The remaining chapter of the first volume is entitled "Synthetic and Natural Sources of the Pyridine Ring", and is both comprehensive (500 pp.), and systematic. Every known synthetic method appears to have been included, and several intriguing, little-known reactions are brought to light. (Is benzene really transformed into pyridine by carbonyl azide ?) Also included is an interesting table of pyridine derivatives which have been encountered in alkaloid degradation reactions. A feature of this chapter is the inclusion of 240 pages of tables, illustrating the scope of each synthetic method in a style reminiscent of *Organic Reactions*. Mechanisms are mentioned only briefly, and Chapter 2 will be valued chiefly as an exhaustive survey of synthetic methods, for as such it is a notable contribution to organic chemistry.

In Volume 2, the detailed discussion of special topics begins, and within its six chapters this volume covers organo-metallic compounds, quaternary compounds and N-oxides, alkyl, aryl, halo- and nitro-pyridines. Each type is discussed systematically under the sub-headings, preparation, properties and reactions, and there is liberal provision of tables at the end of each chapter; these summarize reaction conditions and products, or alternatively list physical constants. Spectral data are rather scarce, and no curves are reproduced. Likewise, little attention is paid to reaction mechanisms; for example, the chemistry of pyridine-N-oxide is described (30 pp.) with the use of only three curved arrows. In fairness it must be admitted that by following the references provided, the reader will be able to find the spectra he is seeking, and will encounter a more mechanistic treatment of the subject. The editor may have preferred to stick to facts, and for a series which is destined to endure for several decades, this is probably a wise decision. Nothing dates a book more than out-moded theory.

The third volume discussed here is entitled *Heterocyclic Systems with Bridgehead Nitrogen Atoms*, Part I. This deals only with fused ring-systems and begins with the smaller rings. (A second volume is planned to complete the discussion of fused systems and to deal with bridged systems.) This is a fascinating book, which assembles and classifies a group of heterocycles, many of which have never before been reviewed. However, it is no mere collection of curiosities. Many of the claims in the literature reported in this book are highly improbable, and the author has been commendably critical in discussing them. The earlier chapters, in particular, are rich in unsolved problems. Later chapters deal with less-obscure topics (for example, pyrrocolines) and provide tables of derivatives. An exhaustive review of penicillin chemistry would have been impracticable and the author has elected to describe only syntheses of the thiazolidine-β-lactam system, and to provide key references.

This volume will probably attract less attention than those mentioned above, but the author is to be congratulated on his treatment of a difficult subject; this is a valuable contribution to the chemical literature. G. L. BUCHANAN

COASTAL INLETS

Stability of Coastal Inlets

By P. Brunn and F. Gerritsen. Pp. xvii + 123. (Amsterdam : North-Holland Publishing Company, 1960.) 23*s*.

THIS book is concerned with the stability of channels connecting estuaries and inlets with the open sea. The depths in such channels are becoming increasingly critical as the dimensions of ships are enlarged ; whereas 30 ft. was a generally acceptable depth fifty years ago, depths of up to 50 ft. are required to accommodate the vessels of 100,000 tons now being built. As a result many estuaries in which important ports are situated are being closely examined—often with the aid of hydraulic models and theoretical studies—to find out if their depths can be increased and their navigational facilities improved. The estuaries of the Rivers Thames, Mersey and Tees are among those being investigated in Great Britain.

These investigations are much handicapped by the lack of sound theoretical foundations on which the design of stable channels in mobile material can be based, especially when the complications introduced by tidal flow and littoral drift have to be considered. By assembling an extensive collection of data on the régime in coastal inlets, and by developing the theoretical foundations on which calculations can be made, the authors of this book have made very valuable contributions to the solution of the complex problems involved in the design of coastal inlets, and in the improvement of existing estuarine channels. The authors are, respectively, head, and associate professor of the Coastal Engineering Laboratory of the University of Florida, and have very extensive experience in coastal investigation.

The book opens with some general remarks on the origin of coastal inlets ; this is followed by a comprehensive review first of the theoretical relationships which have been developed from the dynamical and continuity equations describing tidal flow in inlets, and second, of the theories governing the stability of bed material—ranging from the empirical equations developed by Lacey (1930) to the rational theories of Lane (1958), Chien (1957) and others. The significant forces involved in inlet stability are then considered and a relationship between stability sheer stress, maximum tidal flow and cross-sectional area is given. An analysis of data taken from existing inlets follows, and graphs are given which show how the maximum tidal flows are related to cross-sections for a number of inlets and estuaries in Europe and the United States ; it is demonstrated that the stability sheer stress has a general value of 0·080 lb./ft.^{2}, although particular inlets may have values ranging from about 0·072 lb./ft.^{2} (where littoral drift and sediment loads are low) to about 0·103 lb./ft.^{2} (where littoral drift and sediment loads are relatively high).

Later in the book the methods by which sand is passed across inlets are discussed, and it is suggested that there are two radically different methods of by-passing. If the ratio of predominant littoral drift (cubic yd./yr.) to maximum spring tidal flow (cubic yd./sec.) is greater than 200–300, sand generally crosses the inlet on a submerged offshore bar: if the ratio is less than 10–20 the transfer of sand across the inlet involves the movement of tidal channels, and there is no stable offshore bar.

The book ends with a short section on the design of tidal inlets, and it is pointed out that, for stable inlet conditions, the tidal prism and the maximum tidal flow must be large in comparison with the littoral drift and that a suitable stability sheer stress must be chosen. A comprehensive bibliography is included.

Stability of Coastal Inlets can be recommended to all those interested in the design of new inlets, or the improvement of existing inlets and estuaries.

W. J. Reid

MATHEMATICAL STUDIES IN THE PSYCHOLOGY OF WAR

Statistics of Deadly Quarrels

By Dr. Lewis F. Richardson. Edited by Quincy Wright and C. C. Lienau. Pp. xlvi + 373. (London: Stevens and Sons, Ltd., 1960.) 63*s*.

Arms and Insecurity

A Mathematical Study of the Causes and Origins of War. By Dr. Lewis F. Richardson. Edited by Nicolas Rashevsky and Ernesto Trucco. Pp. xxvi + 307. (London: Stevens and Sons, Ltd., 1960.) 63*s*.

The Strategy of Conflict

By Prof. Thomas C. Schelling. Pp. vii + 309. (Cambridge, Mass.; Harvard University Press; London: Oxford University Press, 1960.) 50*s*. net.

WARS begin in the minds of men. Hence the study of war is essentially a task for psychology, and as such demands scientific treatment. Specialists in other fields have been ready with explanations based on some cherished concept of their own—the instinct of pugnacity, the growth of population or the expansion of trade, the ambitions of nations or their leaders, a society based on acquisitiveness and aggression, carried away by emotional forces similar to those that generate conflict and disharmony in the mind of the individual. But, until quite recently, no one has specialized in research on war psychology as such, or attempted a systematic analysis of the available data to check and verify these alternative theories by the methods of empirical science.

The pioneer in this newer approach was Lewis Fry Richardson. A Quaker by upbringing and a physicist by training, his guiding principle was to study war and peace by the same quantitative techniques that he developed for the solution of apparently intractable problems in the field of physics; and as early as 1919 he published a short pamphlet on *The Mathematical Psychology of War*. His best-known work was in applied mathematics and meteorology. His highly original paper on "The Approximate Solution by Finite Differences of Physical Problems involving Differential Equations" anticipated the method of 'relaxation'; and his book *Weather Prediction by Numerical Process* has been acclaimed as "the first textbook on dynamic meteorology".

In 1926 he was elected a Fellow of the Royal Society; and shortly afterwards, at the age of forty-eight, took an honours degree in psychology. From 1930 until his death in 1953 he devoted himself almost entirely to what he called "generalized foreign politics". His various investigations were collected and embodied in two major books, which, thanks to the generosity of United States scholars and the Littauer Foundation, have now been edited and published.

The first is concerned primarily with the problems and consequences of an 'arms race'. Richardson's plan is to express the underlying tendencies in the form of two differential equations. From these he deduces a variety of corollaries which he then seeks to verify by comparing the theoretical 'predictions' with the actual data for the periods that ushered in the two World Wars. A further deduction, based on the usual method for determining a position of equilibrium, enables him to formulate the conditions that are most likely to ensure a stable balance of power.

His second book treats war as a "large scale example" of what he terms "deadly quarrels"—a phrase which includes any form of human conflict issuing in the death of one or more of the contestants—murder, gangsterism, and banditry, as well as the wars of history. With amazing industry he has compiled a mass of information relating to the causes of the various outbreaks during the years 1820–1929, and supplements it by the data collected by Prof. Quincy Wright for the "wars of modern civilization". He then attempts to estimate the relative importance of the causes commonly alleged by an exhaustive statistical analysis. His chief conclusion is that wars are due to a wide variety, and usually to a plurality, of predisposing and precipitating factors. The mistake of previous theorists was to single out and over-emphasize just one of many. Of the three main groups he considers geographical conditions more important than economic, and psychological more important than either.

Both volumes, however, are restricted to conditions obtaining before the Second World War, and are therefore of greater interest to the historian than to the student of contemporary politics. Dr. Schelling, who is professor of economics and an associate of the Centre for International Affairs at Harvard University, is concerned with newer problems arising from the development of nuclear bombs and intercontinental missiles. His method is to estimate probabilities rather than to measure causal forces; and his mathematical techniques are those of the economist rather than the physicist. He points out that the present situation is no longer one of "pure or absolute conflict", but of "conflict resting on a basis of certain common interests". On either side the policy that results is a series of competitive manœuvres in which each tries to win the maximum advantage for himself without necessarily inflicting an equal disadvantage on the other. In simplified form such situations are dealt with in the 'theory of games' where the game is of the 'non-zero sum' type. The conclusions to which his arguments lead are often unexpected, sometimes paradoxical, but always instructive. He warns us that the analysis he adopts assumes that both sides argue rationally, whereas in practice the behaviour of rival powers is largely influenced by a variety of irrational factors—personal, emotional, or even wholly accidental. This, however, presents problems in political psychology, varying from moment to moment, rather than in political arithmetic. The moral of it all is that, if you want peace, it is not enough to prepare for war, you must seek to understand it.

Cyril Burt

Magnetic Materials in the Electrical Industry

By P. R. Bardell. Second edition (revised). Pp. 320. (London: Macdonald and Co. (Publishers) Ltd., 1960.) 32*s*. 6*d*. net.

THE scope of this book is precisely indicated by its title: it is about magnetic materials, not about magnetism, and it describes their uses rather than, though not to the exclusion of, their general properties. There is a further restriction: the author's interests are mainly in communications and his book is biased accordingly. He is an engineer and his book is primarily for engineers, although it might also interest a physicist who wants to find out the technical relevance of some of the properties he measures. This prying physicist would occasionally raise his eyebrows; for example, at some diagrams of magnetic domain boundaries of types recognized since about 1950 as impossible; but one or two such slips do not affect the general practical usefulness of the book. The only serious lapse is that the author thinks that manganese-zinc and other double ferrites are used for the sake of increased permeability rather than for increased flux-density.

The text uses trade names freely, and for many readers this will be helpful. The book is generously illustrated, both with diagrams which are good and with photographs which do not really add much to the text. The contents pages and index are good. One gem of over-zealous editing is included: a 10^{11} in the manuscript was presumably rendered by the typist as 10" and now appears as 10 in. Fortunately this is not typical; the proof-reading is good and the book is well produced. It packs a great deal of information into a reasonable space and within its intended limited scope it is to be recommended.

A. C. LYNCH

The Physiology of Crustacea

Edited by Talbot H. Waterman. Vol. 2: Sense Organs, Integration, and Behaviour. Pp. xiv+681. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1961.) 23 dollars.

THIS volume completes the survey of physiological processes in Crustacea which was so well begun by the volume published last year. There are thirteen chapters written by separate authors dealing with a wide range of topics, but all related in some way to the means by which a crustacean receives information abouts its environment and the ways in which it responds to this information. The general standard of these chapters is excellent; the two middle chapters by Wiersma on the neuromuscular system and the central nervous system are particularly valuable. They provide a link between the chapters dealing with sensory perception and the chapters on locomotion and complex behaviour. The link is by no means complete yet, but the crustacean nervous system is most economically organized and contains relatively few neurons so that it offers the possibility of a type of analysis which would be much more difficult to achieve in vertebrates. The fourteenth chapter is an attempted synthesis of the two volumes, and might almost be described as a philosophers' guide to comparative physiology.

As in the first volume one is impressed by the amount already known about the physiology of the Malacostraca, and the Decapoda in particular, but one also gains a strong impression that the lower Crustacea are greatly in need of more detailed study. This is one of the great strengths of the book; the gaps in our knowledge are clearly shown.

In a work of this size it is inevitable that a few minor errors should creep in; *Limnadia*, for example, is not a notostracan as might be inferred from Table 1 in the first chapter, and the young stages of *Bosmina coregoni* would not generally be regarded as metanauplii. These errors do not detract from the great achievement of the editor in bringing together these excellent summaries. The information presented and the detailed bibliographies make this book essential to every student of the Crustacea, and provide the general zoologist with a detailed, up-to-date account of the nervous system and behaviour of this large group.

J. GREEN

Sound Production and Sound Reception by Insects

A Bibliography. By Mable Frings and Hubert Frings. Pp. vi+108. (University Park, Pennsylvania: Pennsylvania State University Press, 1960.) 4 dollars.

THIS is a bibliography which will prove useful to the increasing number of students of sound production and hearing in insects. It includes 1,752 titles, and is tolerably complete up to the end of 1957. No annotations are provided but a simple set of symbols indicates the ground covered by each paper or book quoted. The bibliography proper is followed by two indexes which refer to the numbered entries in the bibliography; one is classified under the orders and families of insects, the other under the types of organ used for sound reception. The authors proceed on the assumption that any mechano-receptor may on occasion be brought into service for the detection of waves, vibrations or rapid barometric changes in the surrounding medium, and may serve as an occasional organ of hearing. The bibliography therefore covers a wide field. Modern methods of recording and analysing sounds have attracted more workers into this field in recent years; the present compilation should be widely used.

V. B. WIGGLESWORTH

Doctors and Disease in Tudor Times

By W. S. C. Copeman. Pp. xiv+186+13 plates. (London: Dawson's of Pall Mall, 1960.) 42*s*.

THIS book can be read with pleasure, profit and interest. It is also a book to have by you so that it can be read or referred to again and again.

It begins well with an introduction that is unusual because it is good; it is in itself a concise essay on the importance of, and justification for, presentation of medical history.

The first chapter is especially acceptable because it gives an excellent review of the history not only of medicine but also of Europe as well. The evaluation of the profession is thus presented in its relation to the whole pattern of life and society.

As a whole this book contains in a concise yet clear and readable form valuable information about the historical evaluation of medicine that makes one somewhat disturbed, even ashamed, that it is not generally completely known, so fundamental is it.

In some chapters a certain amount of repetition indicates the origin of the book in separate lectures. While this is noticeable when the book is read as a whole it would not be noticeable when it is used for reference, and in this way the repetition is in fact likely to be helpful.

The author is to be congratulated on such a scholarly, interesting and eminently readable book.

RUSSELL BROCK

SCIENCE IN THE HIMALAYA

By Dr. L. G. C. E. PUGH
National Institute for Medical Research, London

THE Himalayan Scientific and Mountaineering Expedition, 1960–61, led by Sir Edmund Hillary, and which was sponsored by the *World Book Encyclopædia*, recently concluded its operations after a period of nearly ten months in the field. The final stages were marred by an unfortunate series of accidents, due to illness, which led to the withdrawal of the party from its final mountaineering objective—the ascent of Mount Makalu without the use of supplementary oxygen. Nevertheless, the programme of scientific research, both on Mount Makalu and in the Ming Bo region, near Mount Everest, where the party spent the winter, was successfully completed.

The expedition set out from Katmandu at the beginning of September 1960, and returned during May–June 1961. Scientific work was carried on continuously from December to May on the Ming Bo Glacier at an elevation of approximately 19,000 ft. Physiological observations on a smaller scale were made on Mount Makalu at altitudes of 21,000 ft., 24,000 ft. and 26,000 ft.

The winter programme was made possible by the provision of a prefabricated hut designed for the expedition by E. Levin, of the Timber Development Association, Ltd., London. The hut provided complete immunity from the weather, reasonably stable indoor temperatures around 60°–70° F., and excellent lighting. It was a cylindrical structure composed of about 100 sections and weighing approximately 1 ton. The walls consisted of 4-in. thick plywood panels of stressed skin construction, lined with aluminium foil and filled with foamed plastic. Heating was provided by a kerosene stove, designed for operation at 20,000 ft., by the British Petroleum Co.'s Research Centre at Sunbury-on-Thames. Electricity for lighting and scientific apparatus, including a radio transmitter, was provided by a Lucas wind generator and a motor generator, with 24-V. nickel–iron storage batteries. The hut stood on jacks on a snow surface and was held down by steel cables.

The scientific team was organized and led by Dr. L. G. C. E. Pugh, of the Division of Human Physiology, National Institute for Medical Research, and was composed as follows: Mr. B. Bishop, National Geographic Society, Washington (glaciologist); Mr. M. G. Gill, University of Otago, Dunedin, New Zealand (medical student); Prof. S. Lahiri, Presidency College, Calcutta, 12 (physiologist); Dr. J. S. Milledge, University of Birmingham and the Southampton Chest Hospital, Southampton, Hants (physician); Captain T. Nevison, U.S. Air Force Medical School (physiologist); Dr. M. P. Ward, Department of Surgery, London Hospital, Whitechapel, London, E.1 (surgeon); Dr. J. B. West, Department of Medicine, Postgraduate Medical School, Hammersmith Hospital, London, W.12 (physiologist).

Captain B. Motwani, of the Defence Science Laboratory, Delhi, was attached to the Expedition as an observer, and assisted with physiological and other work.

The only non-scientist with the party was W. Romanes, a builder from New Zealand. His knowledge and skill played an important part in the successful erection and maintenance of the laboratory hut and its equipment. He also acted as assistant to B. Bishop in his glaciological and meteorological work.

As may be inferred from the composition of the team, the emphasis in planning the scientific programme had been placed on physiological research. Studies in glaciology and meteorology were also undertaken, but on a more limited scale. A programme of psychometric testing designed by the Medical Research Council's Applied Psychology Unit at Cambridge was carried out by M. Gill, as well as tests of the special senses of hearing and vision.

The principal physiological investigations carried out during the winter were as follows:

(1) *Functions of the heart.* The cardiac output was measured by the acetylene technique in men exercising at three work intensities on a bicycle ergometer. Serial electrocardiograms were taken at intervals throughout the expedition.

(2) *Pulmonary function.* The diffusing capacity of the lungs for carbon monoxide and oxygen was measured at three grades of muscular exercise.

(3) *Respiratory regulation.* The response threshold and sensitivity of the respiratory centres to carbon dioxide and the interaction with oxygen were studied, using a technique worked out by Lloyd and Cunningham, and their associates in the Department of Physiology at the University of Oxford.

(4) *Respiratory exchanges.* Oxygen-consumption, lung-ventilation and heart-rate were measured under basal conditions and during muscular work at 300, 600 and 900 kgm./min. on the bicycle ergometer. Data were obtained on the effect of breathing supplementary oxygen.

(5) *Blood.* Samples of arterialized venous blood from the heated hand at rest and during exercise at three rates of work were analysed for oxygen and carbon dioxide. The arterial oxygen saturation at rest and exercise was also followed, using a Waters Conley ear oximeter. The effect of a prolonged sojourn at altitude on blood volume, hæmatocrit, red cell and hæmoglobin concentration was studied.

(6) *Renal function.* The following tests were carried out: maximum and minimum *p*H of urine after suitable doses of sodium bicarbonate and ammonium chloride, respectively; the maximum specific gravity during water deprivation; maximum water elimination after a standard water load.

On Mount Makalu (27,900 ft.) the respiratory exchanges were measured on subjects working on the bicycle ergometer at 21,000 ft. and 24,000 ft. and electrocardiograms were recorded at both of these camps. Twenty-five samples of alveolar air were taken at 26,000 ft. and brought back to London for analysis.

Results

Preliminary results of some of these investigations are already available, having been worked out before leaving the Himalaya. The principal findings were as follows:

The electrocardiographic records obtained at 19,000 ft. showed marked right axis deviation, which was not abolished by breathing oxygen. The output of the heart for a given work-load on the bicycle ergometer was somewhat lower than the control values at sea-level; the maximum output was limited to 16–18 l./min. compared with 25–30 l./min. at sea-level. Heart-rates at low work intensity were higher than sea-level control values at the same work-rate, but during maximum work the heart-rate was comparable with or lower than the corresponding sea-level value. Maximum heart-rates were limited to 130–150 beats/min. compared with 180–190 beats/min. at sea-level.

The diffusing capacity of the lungs for carbon monoxide and oxygen during exercise was not significantly altered by prolonged residence at altitude, the results being closely comparable with control values obtained at sea-level. Arterial blood-oxygen saturations of 65–70 per cent were observed in resting subjects at 19,000 ft. During severe muscular exercise arterial oxygen saturations fell to 50–55 per cent—values which would not be consistent with consciousness in unacclimatized subjects acutely exposed to lack of oxygen.

It was found possible to work for up to 5 min. at 900 kgm./min. on the bicycle ergometer at 19,000 ft. and 1,200 kgm./min. could be kept up for 2 min. by the fittest subjects. These work intensities were very much higher than those studied by previous investigators. Maximum oxygen intake during exercise at 19,000 ft. was 2·0–2·5 l./min. compared with 3·5–4·0 l./min. at sea-level when the subjects were less fit. Ventilation volumes of 120–150 l./min. body temperature, pressure, saturated were observed during sub-maximal work (900 kgm./min.), but at 1,200 kgm./min. values as high as 200 l./min. were recorded just before the breaking point. These results confirmed previous observations made on Mount Everest in 1953.

The studies of respiratory regulation indicated that the increased breathing at altitude is accounted for partly by a lowering of the threshold of response to carbon dioxide and partly by an increase in sensitivity to carbon dioxide. The interaction between oxygen and carbon dioxide, whereby carbon dioxide sensitivity increases at low oxygen tension, was not apparently affected by acclimatization to altitude.

Blood-volumes measured by the carbon monoxide method showed a small but significant reduction after 4–6 weeks at altitude; after 4–6 months, however, four out of six subjects studied showed major increases in blood-volume amounting to about 1 litre. The remaining two subjects showed no late increase in blood volume, and their hæmoglobin concentration and hæmatocrit values declined. It was thought that this might be associated with high-altitude deterioration.

Meteorology

Fine weather with clear skies prevailed throughout the autumn and winter. Apart from afternoon mist and a few short storms, the fine weather continued until the end of April, when the pre-monsoon period of unsettled weather set in.

The lowest temperature recorded was −27° C. Winds of 45 knots gusting to 60 knots were common during the winter, and it was seldom necessary for the motor generator to be used. In April, calm weather prevailed.

These observations, which are the first to be made at high altitude during the Himalayan winter, suggest that a safer time for climbing operations might be autumn or early spring rather than the traditional pre-monsoon season.

THE CHESTER BEATTY RESEARCH INSTITUTE (OF THE INSTITUTE OF CANCER RESEARCH: ROYAL CANCER HOSPITAL)

By PROF. A. HADDOW, F.R.S.
Director

AN extension of the Chester Beatty Research Institute (see Fig. 1) was opened by Sir Howard Florey, president of the Royal Society, on June 9, in the jubilee year of the formal inauguration of the Research Institute of the then Cancer Hospital (Free), by H.R.H. the Duke of Connaught on May 23, 1911. The main cost of the new construction was defrayed from funds contributed in the past by the charitable public, approximately £250,000 having been made available to the Committee of Management of the Institute of Cancer Research by the Board of Governors of the Royal Marsden Hospital, the latter acting as custodians. In addition, a grant of £40,000 was made by the Wellcome Trust, in recognition whereof a section of the extension has been designated the Wellcome Laboratory, for research in pharmacology and experimental chemotherapy. The new building, of which the architects were Messrs. Lanchester and Lodge and the contractors Messrs. Humphreys, is linked on four floors with the older Chester Beatty Research Institute, and contains extensive animal-house accommodation, laboratories in biology, organic chemistry, biochemistry, physical chemistry, immunology and cytogenetics, and a conference hall to seat approximately 180. The opportunity has also been taken to re-model the older building, and, among other things, to provide increased library facilities. The present scientific staff at the Fulham Road site, together with an experimental station at Pollards Wood, Chalfont St. Giles, Buckinghamshire (directed towards work on biological mutation, tracer biochemistry, nucleic acid chemistry, protein synthesis and virology), numbers about one hundred, with an approximately equal number of technicians.

It may be of interest to summarize the history of the institution over the past fifty years. The Cancer Hospital (Free), of which the Institute was to become

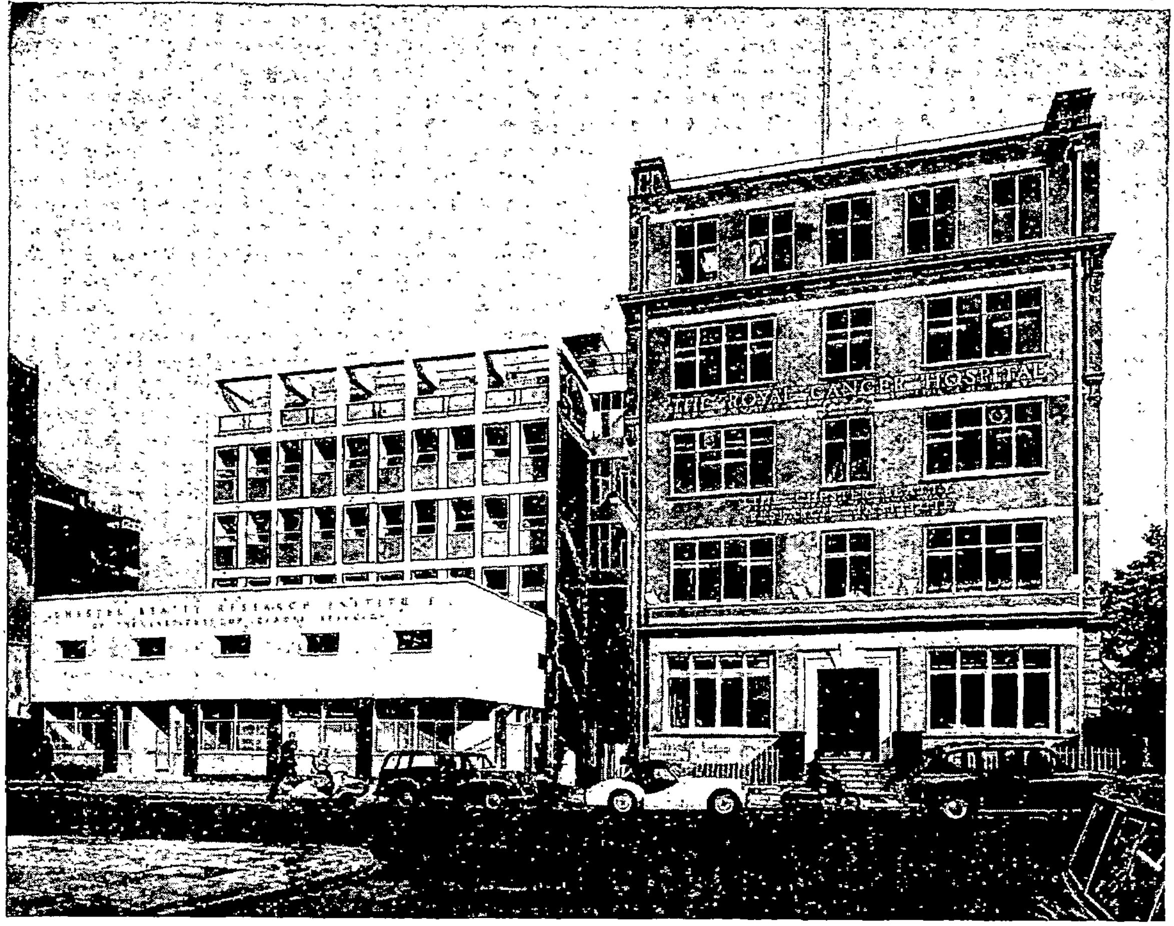

Fig. 1. The Chester Beatty Research Institute and the New Extension

a part, was founded by Dr. William Marsden in the year of the Great Exhibition. At St. Bartholomew's Hospital, Marsden was among the last students of John Abernethy, who had been surgical dresser to Sir Percivall Pott, in turn author in the latter part of the eighteenth century of a celebrated description of cancer of the skin as an occupational disease of chimney sweeps (due to contamination of the skin with soot)—a key observation in direct line with the great advances made by Kennaway and his school, at the Institute, 150 years later.

From its foundation, the Cancer Hospital soon achieved a considerable tradition of clinical research and discovery. However, at the turn of the nineteenth century, increasing recognition of the need for the experimental method led in due course to the establishment of a Research Institute, in 1909. Almost thirty years later its facilities proving inadequate, the Institute was transferred to new quarters in 1939, through the benevolence and vision of Sir Chester Beatty, in recognition of which the Institute was re-named. In the meantime, the Institute, with parts of the Physics and Radiotherapy Departments of the Hospital, had for several years been recognized as a School of the University of London.

With the advent of the National Health Service in 1948, the Institute became the nominal responsibility of the Ministry of Health. Very soon, however, mutual arrangements were made whereby the main financial responsibility was assumed by the Medical Research Council, and the Institute became affiliated to the British Postgraduate Medical Federation. Very necessary additional finance is provided by the British Empire Cancer Campaign, which has supported the Institute increasingly over the past thirty-eight years, and also on a substantial scale from the United States Government through its Public Health Service, and to a lesser, but valued, extent from private American benefactions such as the Jane Coffin Childs Memorial Fund for Medical Research, and the Anna Fuller Fund, of New Haven and Yale.

The first director was Alexander Paine, most noted for his work with Poynton on *Streptococcus rheumaticus*. In its earliest days the Institute rapidly attracted an extraordinary group of men—including Charles Singer, Schryver (its first physiological chemist), Keith Cannan (now of the National Research Council in Washington), Casimir Funk, Jack Drummond, G. W. Nicholson and E. H. Kettle. Casimer Funk, who at that time was studying the etiology of the deficiency diseases (beriberi, polyneuritis, epidemic dropsy, scurvy and pellagra), had coined the name 'vitamine' in 1912 (while at the Lister Institute), and joined the staff in 1913. Drummond himself joined Funk in 1914, and was appointed to succeed him as physiological chemist in 1918. During these years Drummond carried out much remarkable work, in advance of its time, on the amino-acid composition of tumours, and, later, it was he who advocated dropping the final 'e' of 'vitamine', so that the word 'vitamin' should be acceptable under the Chemical Society's scheme of nomenclature.

In 1920, Paine was succeeded by Archibald Leitch. Dogged by ill-health, Leitch nevertheless deserves the utmost credit for giving the Institute its continuing theme—chemical carcinogenesis and its mechanisms—and, during his directorship, which coincided with a period of great stimulus following the discovery by the Japanese, in 1915–18, that cancer could be artificially produced by long-continued application of coal-tar to the skin of the rabbit or mouse, wrote several papers of classical merit.

On Leitch's death, he was succeeded in 1931 by E. L. Kennaway, who had been appointed physiological chemist ten years before. In the 1920's, Bloch and his co-workers in Zurich had already adduced evidence to suggest that the active agent in coal-tar might well be a cyclic hydrocarbon. Of this, Kennaway supplied a virtual proof, through the generation of artificial carcinogenic tars, either by passing isoprene or acetylene with hydrogen through heated tubes, or by the pyrolysis of natural products. Study by Mayneord of the ultra-violet fluorescence properties of carcinogenic tars led to recognition of a (largely) characteristic spectrum, and this essential clue in turn resulted in the detection by Hieger of the same spectral qualities in 1 : 2-benzanthracene, the discovery of the first chemical individual to manifest pronounced carcinogenicity (1 : 2-5 : 6-dibenzanthracene), the isolation by Cook, Hieger and Hewett in 1933 of 3 : 4-benzpyrene from carcinogenic pitch, and the generation (following a prediction by J. W. Cook) of the potent carcinogen 20-methylcholanthrene from deoxycholic acid.

In these earlier days it seemed possible that the cyclic aromatic hydrocarbons might exercise some specific function in carcinogenesis, and it is still not to be excluded that, by their formation in even trace amounts through local abnormalities of steroid metabolism, they could play an important part in the natural causation of cancer in man. However, the experimental findings of the past thirty years have shown beyond question that carcinogenicity is equally a property of many other chemical types, among which may be included various azonaphthalenes studied by Kennaway himself, a series of aminostilbenes described by Haddow, Harris, Ross and George Kon, many instances of endocrine carcinogenesis in the work of Harold Burrows and Eric Horning, and a range of polymers, plastics and metals—to name but a few.

In the past fifteen years, attention has naturally become centred on problems of the mechanisms of action. The mode of action of the hydrocarbons themselves and of the aromatic amines is still obscure, although valuable progress has been made through the investigations by Boyland and his group of the intermediary metabolism of such agents. It is probably true to say that of all the groups of carcinogenic agent more recently recognized, the now very large class of so-called biological alkylating agents is the most important. Of some practical relevance in that they have yielded chemotherapeutic agents such as 'Myleran', 'Chlorambucil' and 'Melphalan' of useful application in the treatment of chronic myelogenous leukæmia, chronic lymphatic leukæmia and myelomatosis respectively (from the work of F. Bergel, G. M. Timmis, W. C. J. Ross, D. A. G. Galton, L. A. Elson, and others), their main importance is, however, fundamental. The father of these modern developments seems to have been no other than Paul Ehrlich, who at the turn of the century (many years before the demonstration of chemical carcinogenesis or of chemical mutation) was convinced of the unique quality of ethyleneimine (among many hundreds of compounds of which he had experience), in its capacity to effect irreversible interactions with receptors in 'protoplasm', of much significance (as he thought) for cellular heredity.

Certain it is that the alkylating agents, from their relative simplicity and chemical reactivity, possess numerous advantages in the elucidation of carcinogenic mechanisms. Within the Institute, detailed studies of their cytological effects (by P. C. Koller and S. H. Revell), and of the dependence of many of the biological properties on a minimum chemical reactivity and a bi- or poly-functional structure, led Goldacre, Loveless and Ross twelve years ago to propose the cross-linkage hypothesis, with implications for the chemical cross-linkage of contiguous linear macromolecules perhaps within the chromosome structure itself. The hypothesis in its early form is now known to be over-simplified, and is not, for example, applicable to biological mutation at large. Yet it proved highly fertile in development, and rapidly led to recognition of new alkylating types of biological interest, a process in which much help was gained from the field of textile technology.

A key problem concerns the relative importance of the reactive groups in proteins, nucleic acids and nucleoproteins, which may be the centres of attack—with special reference to the striking dethiolating properties of 'Myleran' studied by J. J. Roberts and G. P. Warwick, to the esterification of phosphate groups brought about by other alkylating agents (P. Alexander, W. C. J. Ross), and to alkylation of the purine and pyrimidine bases. Involvement of purines was reported by Press and Butler some years ago, and later work by Lawley showed the special importance of *N*-alkylation at the 7-position of guanine. Of special interest is the possibility that esterification of phosphate groups, and alkylation of purine moieties, may represent consecutive steps in a reaction leading to delicate interference with the integrity of the nucleic acid structure. Most recently, Lawley and Brookes have recovered, among other products of the reaction of both sulphur and nitrogen mustards, *bis*-guanyl structures which very likely—although there is no formal proof—reflect cross-linking of the twin spirals of the Crick–Watson helix.

In general, the work of the Institute points towards a conclusion identical with that being reached by many other laboratories using different lines of attack, namely, that malignant transformation may involve biochemical deletion, with permanent release from those enzymic systems responsible for homeostasis of the growth potential of the normal cell. Diverse as are not only chemical but also physical and viral carcinogens, in their nature and modes of operation, and indeed in the tumours they produce, it is still not to be excluded that they may, by varied routes, lead to a key alteration similar or even identical in the various cases; and it is towards some such synthesis that the work of the Institute will continue to be directed.

METABOLIC PRODUCTION OF SUCROSE FROM FAT

By Prof. H. BEEVERS

Department of Biological Sciences, Purdue University, Lafayette, Indiana

THE production of sucrose from reserve fat occurs on a large scale in some germinating seeds. For example, an ungerminated castor bean contains some 260 mgm. of fat (70 per cent of its dry weight) and 15 mgm. of total carbohydrates[1]. During germination at 25° C. in the dark over a period of 8 days the total fat content of the seedling falls to about 50 mgm. while the carbohydrate rises to 230 mgm., and this is in spite of the fact that sugars are being used extensively in the growth and respiration of the seedling proper. Thus there is a production of more than 1 gm. of sugar (principally sucrose) for each gram of fat consumed. This interconversion is strictly confined to the endosperm tissue (respiratory quotient (RQ) about 0·35); sucrose moves into the growing seedling where it supports carbohydrate respiration (RQ = 1·0).

In considering the pathway of this interconversion, we should note first that glycerol is converted quantitatively into sucrose in the endosperm and quite efficiently in the cotyledons also[2]. The labelling pattern in the hexose produced from glycerol-1,3-^{14}C shows that the intact 3-carbon unit is incorporated, presumably after conversion to triose[2]. It should be clear, however, that the synthesis of sucrose from the glycerol moiety of the fat could account for only a small fraction of the conversion actually observed. Thus the problem resolves into the synthesis of sucrose from long-chain fatty acids.

The metabolism of fatty acids in plant tissues has been intensively investigated by Stumpf *et al.*[3]. Although enzymic mechanisms inducing α-oxidation engaged earlier attention, the metabolism of specifically labelled acids by tissue-slices pointed to the operation of a β-oxidation pathway *in vivo*, and such a sequence has indeed been shown to occur in mitochondria from peanuts and other tissues when these were suitably fortified with co-factors. Formidable problems remain in elucidating the details of utilization of the unsaturated acids, but it seems safe to conclude that the breakdown results in the production of acetyl coenzyme A (CoA)[3]. Certainly the efficiency of the overall conversion of fat to carbohydrate is such that the loss of carbon as carbon dioxide during the production of 2-C units must be very small indeed.

Now it has been established that acetate is utilized readily by slices of endosperm tissue[4]. In a 9-hr. experiment in which specifically labelled acetates were provided, it was found that at least 33 per cent of the added carboxyl carbon and 68 per cent of the added methyl carbon were converted to sucrose; the amounts converted to carbon dioxide were 46 per cent and 10 per cent, respectively. This net synthesis of sugar from acetate, with little diversion to other products, posed a problem analogous to that presented by those microbial cells which can grow on acetate as a sole source of carbon. The elucidation of the glyoxylate cycle[5], by which a net synthesis of a 4-C acid such as malate can be achieved from two acetate units, offered a basis for its solution. An examination of castor bean tissues showed that the requisite enzymes, and particularly those newly described from micro-organisms, malate synthetase and isocitratase, were indeed present. A proposal was made, therefore, that the pathway of synthesis involved the production of a dicarboxylic acid by the glyoxylate cycle followed by conversion of malate into hexose[6]. Since this time we have carried out extensive experiments on tissues of fatty seedlings and extracts which have confirmed this suggestion and firmly establish the pathway of sucrose synthesis from acetate in such material. This evidence will now be summarized.

Distribution and Capacity of the Enzyme Systems and Changes during Germination

The demonstration that isocitratase was present in the germinating castor bean raised the possibility that it was widespread in plants and accounted for the general occurrence of glyoxylate and its reduction product, glycollate. An examination of some twenty-five different tissues revealed that this was not so[7]. Far from being widespread, the enzyme was shown to be confined strictly to tissues rich in fat, particularly those of germinating seedlings. Furthermore, it was shown to be localized, in these seedlings, to those tissues in which fat is converted to sugar; it could not be detected in the adjacent parts of the seedling proper. No activity was found in the ungerminated seed or in the maturing seed on the parent plant. During the first few days of germination the enzyme activity rose dramatically and a peak was reached at about the time fat breakdown and sucrose synthesis were most rapid. Later on, as the fat content declined, so did the activity of the isocitratase. It is most significant that this decline in

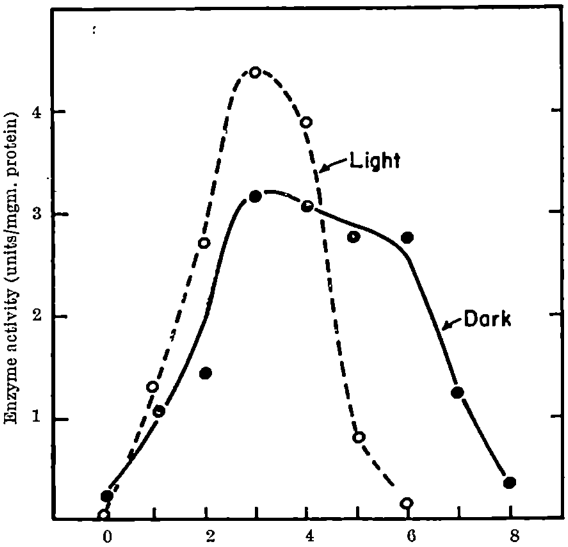

Fig. 1. Changes in isocitratase activity during germination of *Cucurbita pepo* (pumpkin) seeds
One set was exposed to light during the germination period and greening of the cotyledons occurred (ref. 7)

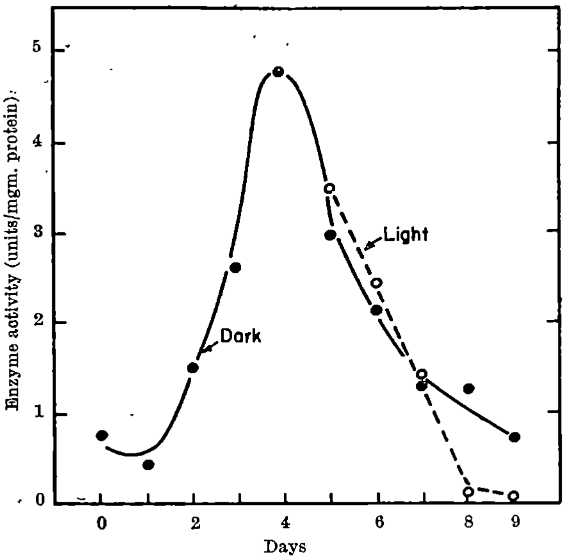

Fig. 2. Changes in malate synthetase activity during germination of *Cucurbita pepo* (water melon) seeds
One set of seedlings was exposed to light during the germination period and greening of the cotyledons occurred (Yamamoto and Beevers, unpublished)

isocitratase activity was not confined to seedlings, such as the castor bean, in which the fat reserves are in tissue which is completely absorbed during germination: it is noticed also in those seedlings the fat of which is originally present in cotyledons which persist as functioning leaves during the later growth[7]. Fig. 1 shows results obtained with seeds of the latter type. The fall in isocitratase activity occurred whether or not the cotyledons were allowed to become functional green leaves.

Malate synthetase was also found in the endosperm or cotyledon tissue of every fatty seedling examined, and it, too, showed changes in activity which paralleled the changing pace of fat breakdown[8]. It is again of interest that malate synthetase activity disappears from the cotyledons of cucurbits after the fat has been utilized (Fig. 2), since this implies a selective breakdown or inactivation of those enzymes constituting the glyoxylate by-pass at a time when other metabolic machinery is operating smoothly. Malate synthetase is not widespread in plants. Although the richest sources are fatty seedlings, it has been detected in a few tissues, for example, corn embryos, which are not primarily engaged in converting fat into sugar[8].

Isocitratase[7] and malate synthetase[9] have been partially purified from castor beans and their properties are similar to enzymes isolated from other sources. Both show an absolute requirement for divalent metal ions and are maximally activated by magnesium ions; in addition, the isocitratase shows a requirement for a compound containing —SH groups (gluthathione, cysteine). The presence of these enzymes in germinating fatty seeds has been confirmed and the amounts which can be extracted are adequate to account for the rate of sucrose production observed *in vivo*[6,8,10–12]. There is evidence that mitochondria prepared from fatty seedlings contain each of the enzymes of the glyoxylate cycle[11], but isocitratase and malate synthetase are found also in the supernatant solutions from such preparations.

Each of the enzymes which would be required to convert malate to sucrose by the following pathway has been shown to be present in the endosperm of germinating castor-oil seeds[13].

malate → oxalacetate → phosphoenolpyruvate → phosphoglycerate → di-phosphoglycerate → triose phosphate →
hexose phosphate → sucrose

The formation of phosphoenolpyruvate and phosphoglycerate from oxalacetate is brought about by phosphoenolpyruvate carboxykinase. Adenosine triphosphate (ATP) is required for this step and for the formation of diphosphoglycerate in the phosphoglyceryl kinase reaction. It is of interest that two triosephosphate dehydrogenases are present, one requiring diphosphopyridine nucleotide (DPN) and the other triphosphopyridine nucleotide (TPN) as a coenzyme[14]. Of the two known systems which might bring about sucrose synthesis from hexoses, only the uridinediphosphoglucose – fructose transglucosylase was found to be present[15]. The 'assimilatory power' (ATP and reduced TPN or DPN) required for driving these reactions *in vivo* most probably is part of that produced during the oxidation of the long-chain fatty acids to acetyl CoA.

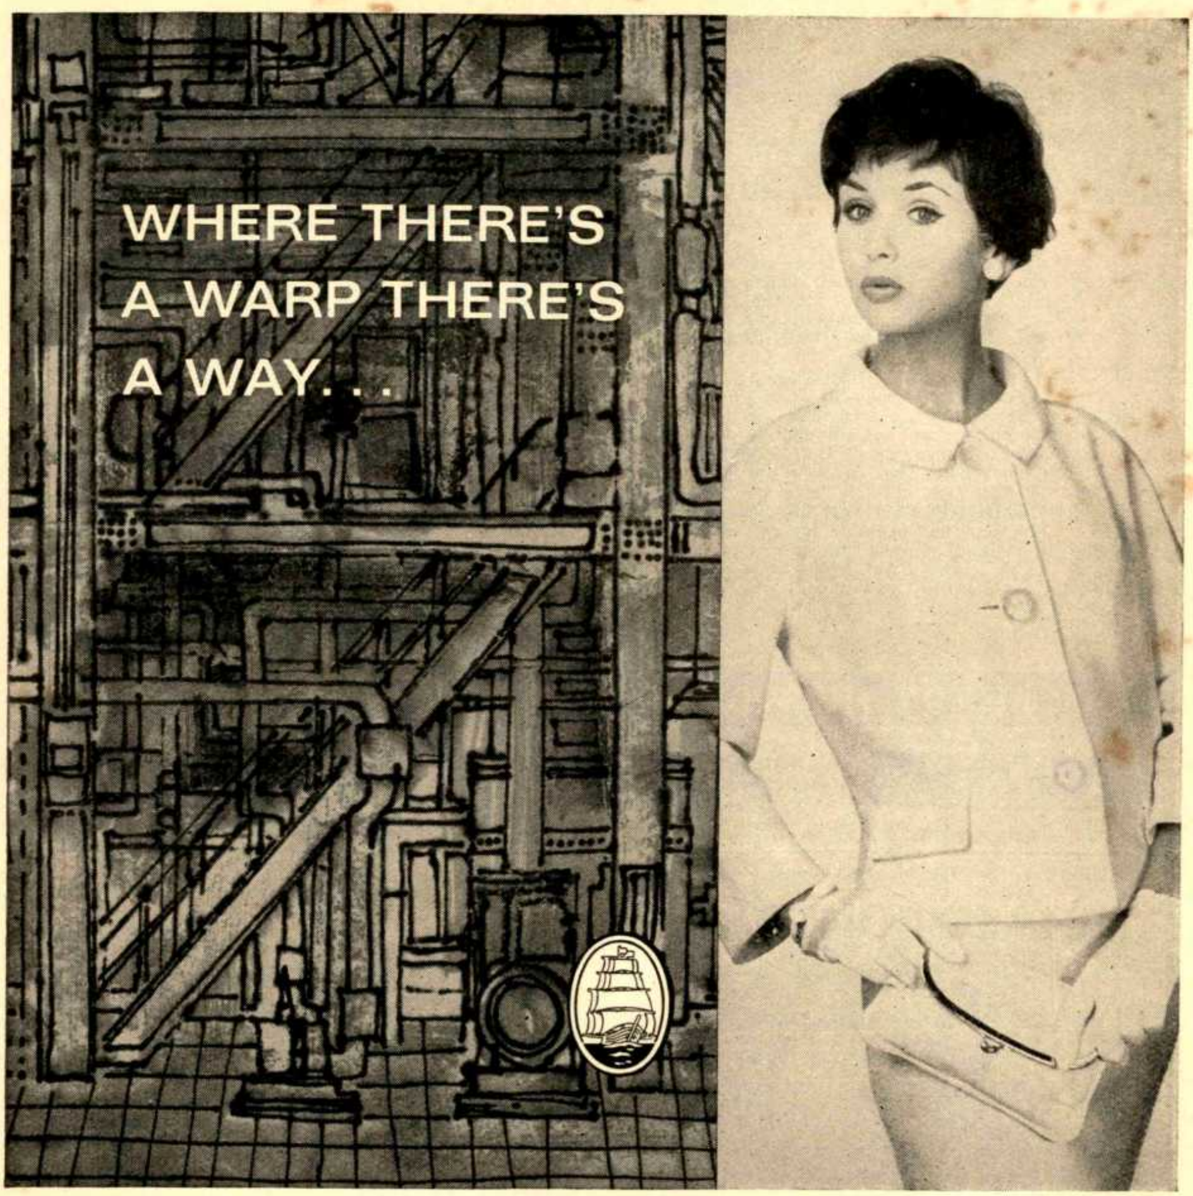
The experiments with cell-free extracts establish, therefore, that the enzymic equipment for carrying out a net synthesis of sucrose from acetate is present in the germinating castor bean. The distinctive distribution pattern and activity changes of malate synthetase and isocitratase in seedlings coincide remarkably well with the occurrence and timing of the fat → sucrose conversion. Experiments with intact tissues, which establish that such a sequence is indeed operative *in vivo*, are outlined in the next section.

Utilization of Acetate and Other Intermediates in Sucrose Synthesis

The earlier results on acetate-utilization[4] are accommodated for the sequence outlined. We have now completed an investigation of the kinetics of acetate-utilization over shorter periods in order to establish what the intermediate products are and the pathway of their interconversion. It will be realized that if the sole fate of acetate is conversion to malate in the glyoxylate cycle and then conversion to sucrose by the sequence above, the methyl carbon atom of acetate would be found only in the centre carbon atoms of malate, none would appear as carbon dioxide and it would contribute equally to carbon atoms 1, 2, 5 and 6 of the hexose units. Half the carboxyls of acetate would be lost in the conversion of oxalacetate to phosphoenolpyruvate and half would appear in carbon atoms 3 and 4 of the hexose. In the recent work with castor bean endosperm slices these predictions have been remarkably well fulfilled. In the meantime, Bradbeer and Stumpf[10] have presented valuable data from experiments with sunflower and peanuts which established that in these tissues also the products isolated after several hours in contact with labelled acetate and labelling patterns in malate and hexose were largely those predicted from the operation of the sequence as outlined.

When acetate-1-^{14}C and acetate-2-^{14}C were supplied to slices of endosperm tissue from castor bean the following results were obtained[16].

(*a*) After 2 min., and before any carbon-14 was present in sugars, virtually all the radioactivity was recovered in organic acids (other than acetate). Support for the dual entry of acetate into the gly-



A PROBLEM that persistently perplexed the linen industry was the excessive friction between warp threads, and between warp and weft, in the weaving process. Production suffered when threads became snarled—and often snapped. The Linen Industry Research Association came to Price's with the problem. Result: Price's have developed Estol 22, a universal size lubricant which has proved to be a complete answer to the industry's problem.

PRICE'S RESOURCES—AND RESOURCEFULNESS—which produced Estol 22 in co-operation with the Linen Industry Research Association—are freely available to assist all divisions of industry with their problems. You are invited to take full advantage of Price's wide experience, and the unique facilities at our Bromborough Pool plant for creative oleochemical research, pilot-scale development, and on-the-spot technical sales service.

Can you discharge ·01 microlitres from a direct-reading syringe?

With a HAMILTON ONE-MICROLITRE capacity syringe you can—very accurately and very easily! It utilizes the needle bore to contain the liquid (which means no "dead" volume) and the readings are taken from the normal glass syringe barrel—**as robust and easy to read as a 50-microlitre model** (Fig. 1).

HAMILTON SYRINGES are available in **six models from 1 to 500-microlitre capacity**—and all are available with a Chaney adaptor (Fig. 2), an ingenious device limiting the descent of the plunger and ensuring high accuracy and reproducibility in repetitive injections. The 10-microlitre model has a special plunger guide (Fig. 3) making it as sturdy as a 100-microlitre syringe.

HAMILTON SYRINGES are an invaluable aid in any laboratory and indispensable for gas chromatography. Gas tight models are available, too (Fig. 4), from 0.1 to 10 ml. capacity.

Write your name and address in the margin and send us this advertisement. We will send you our illustrated leaflet by return.

514

oxylate cycle is provided by the finding that malate and citrate were the most heavily labelled acids.

(*b*) As shown in Fig. 3 the percentage of carbon-14 in the acid fraction declined steeply during the experiment and extrapolated clearly to 100 per cent at 'zero' time while that in the sugar fraction increased with time. This pattern establishes that a precursor–product relationship holds for the organic acids and the sugars.

(*c*) At 2 hr., when some 60 per cent of the added acetate had been utilized, the contributions of C-1 and C-2 to sucrose and carbon dioxide are those predicted (Table 1). Relatively small amounts of ^{14}C remain in other fractions; the low incorporation into amino-acids, which arise secondarily from the organic acid, should be especially noted.

Table 1. UTILIZATION OF ACETATE CARBONS BY ENDOSPERM SLICES (Data of Canvin and Beevers, ref. 16)

	Per cent of added carbon-14 in components after 2 hr.			
	Sugars	Carbon dioxide	Amino-acids	Organic acids
Acetate-1-^{14}C	40	2	7	10
Acetate-2-^{14}C	22	22	6	13

(*d*) Degradation of malate isolated after supplying acetate-2-^{14}C showed that at all times after 2 min. the label was equally distributed between carbon atoms 2 and 3, and even after 120 min. these carbon atoms contained more than 90 per cent of the total carbon-14 in the malate. When acetate-1-^{14}C was the substrate, the carbon-14 was exclusively confined at all times to C_1 and C_4 and equally distributed between them.

(*e*) ^{14}C-glucose-6-phosphate was detected in the acid fraction during ^{14}C-acetate utilization.

(*f*) The first labelling in the sugar fraction appeared after 5 min. exposure to the labelled acetate. At this time sucrose was labelled equally in its component hexoses but free glucose and fructose were not radioactive. At later times, when the carbon-14 in sucrose was increasing rapidly, the total radioactivity in glucose and fructose was never more than 6 per cent of that in sucrose, and the specific activity (c.p.m. per mgm. carbon) of the component hexoses was quite close to that of sucrose. Evidently, sucrose is the first and major free sugar produced, and the hexoses arise secondarily from this.

(*g*) Degradation of the glucose moiety of the sucrose produced by endosperm slices incubated with labelled acetates is shown in Table 2. At all times the distribution is close to that predicted; the methyl group of acetate is found equally in carbon atoms 1, 2, 5 and 6, while the carboxyl carbon appears equally in carbon atoms 3 and 4. (See also results from 3-hr. experiments with sunflower and peanut tissue by Bradbeer and Stumpf[10].)

Table 2. PER CENT DISTRIBUTION OF CARBON-14 IN GLUCOSE MOIETY OF SUCROSE ISOLATED FROM ENDOSPERM SLICES INCUBATED WITH CARBON-14 ACETATE FOR THE TIMES INDICATED (Data of Canvin and Beevers, ref. 16)

Substrate	Acetate-1-^{14}C				Acetate-2-^{14}C			
Carbon atom of glucose	Min. 15	30	60	120	Min. 15	30	60	120
1	3·2	5·8	4·9	8·0	22·5	21·5	21·9	22·5
2	6·0	4·8	5·3	12·2	23·8	24·5	23·8	24·0
3	32·9	37·1	38·7	35·3	2·5	4·7	6·0	3·6
4	43·5	37·6	41·6	29·2	3·7	5·3	8·8	9·6
5	7·4	8·2	5·4	7·2	23·0	21·1	20·8	16·6
6	7·0	6·4	4·0	8·0	24·5	22·7	18·8	23·4

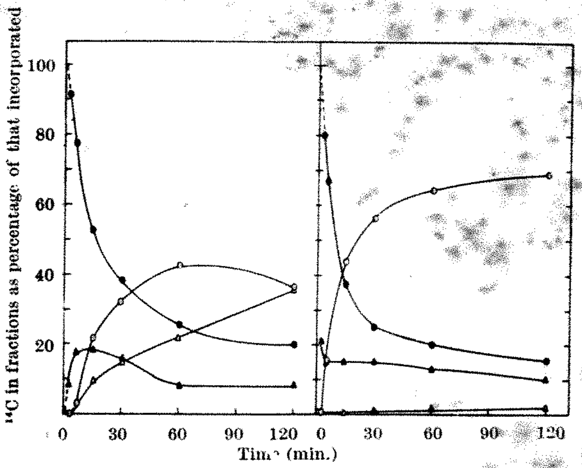

Fig. 3. Changes in carbon-14 content of water-soluble components and carbon dioxide during exposure of slices of castor bean endosperm to acetate-1-^{14}C (left) and acetate-2-^{14}C (right; ref. 16) ⊙, Sugars; *Δ*, carbon dioxide; ●, organic acids; ▲, amino-acids

The distinctive contributions of C-1 and C-2 acetate to the final products, the order of appearance of these carbon atoms in the various components and the degradation data are thus seen to be in good agreement with the proposed sequence.

Experiments with Other Labelled Substrates

(*a*) *Succinate and malate.* In contrast to acetate, which is rapidly absorbed and utilized, the dicarboxylic acids apparently penetrate poorly; the bulk of the added acid (about 80 per cent) was recovered from the medium, even after 8 hr. However, of the acid that did penetrate, a considerable fraction was metabolized to carbon dioxide or sugar. Furthermore, the relative contributions of the carboxyl and centre carbon atoms to these products are those predicted. Thus the carboxyl groups appeared equally in sucrose and carbon dioxide while the centre carbon atoms of succinate made a much larger contribution to sucrose[16] (Table 3).

Table 3. DISTRIBUTION OF RADIOACTIVITY IN CARBON DIOXIDE AND SUGAR FORMED FROM ^{14}C-LABELLED DICARBOXYLIC ACIDS (Data of Canvin and Beevers, ref. 16)

	Time of incubation (hr.)	Radioactivity (c.p.m.)		Ratio Carbon dioxide/sugar
		Carbon dioxide	Sugar	
Succinate-1-^{14}C	4	617	610	1·01
Malate-^{14}C	8	1,189	886	1·34
Succinate-2-^{14}C	4	662	4,593	0·144

Table 4. INCORPORATION OF PYRUVATE CARBON ATOMS INTO ENDOSPERM CONSTITUENTS (Data of Neal and Beevers, ref. 17)

Labelled pyruvate	1-^{14}C	2-^{14}C	3-^{14}C
	Percentage of added radioactivity in component		
Carbon dioxide	49·3	23·8	2·9
Sugars	7·5	15·1	22·8
Organic acids	1·1	8·0	8·5
Amino-acids (alanine)	32·2	29·5	33·2

Equal samples of endosperm slices were incubated with the particular labelled pyruvate for 4 hr.

(*b*) *Pyruvate.* As shown in Table 4, pyruvate is actively converted into sucrose by endosperm slices, but the individual carbon atoms contribute in very different measure[17]. Carbon from positions 2 and 3 accounts for 85 per cent of that appearing in sucrose, with C-3 contributing about twice as much as C-2. The relative contributions to respired carbon dioxide are precisely in the reverse order. About one-third of the added pyruvate is converted to alanine (each of the pyruvate carbons contribute equally) and the acids of the glyoxylate cycle are much more heavily labelled from C-2 and C-3 of pyruvate than from C-1. It is thus seen that C-2 and C-3 of pyruvate behave in a similar manner to C-1 and C-2 of acetate. There is no evidence for a direct conversion of the intact pyruvate skeleton which would require a complete reversal of glycolysis; the conversion of C-1 of pyruvate to sucrose can be ascribed to re-fixation of the carbon dioxide released from this position[18]. The results indicate that pyruvate is converted to acetyl CoA and enters the glyoxylate cycle. Apparently the entry into the glycolytic sequence is indeed at the level of phosphoenolpyruvate, as seemed likely from other considerations[19]. On the basis of the foregoing evidence we may summarize the process of sucrose-formation from fatty acid as follows:

$$\begin{array}{l}
\text{C16 fatty acid} \xrightarrow{\beta\text{-oxidation}} \text{8 acetyl CoA} + 28\ [\text{H}] \\
\text{8 acetyl CoA} \xrightarrow{\text{glyoxylate cycle}} \text{4 oxalacetate} + 24\ [\text{H}] \\
\text{4 oxalacetate} + 8\ \text{H} \xrightarrow{\text{glycolysis reversed}} \text{sucrose} + 4\ \text{CO}_2 \\
\hline
\text{C}_{16}\text{H}_{32}\text{O}_2 + 11\ \text{O}_2 \longrightarrow \text{C}_{12}\text{H}_{22}\text{O}_{11} + 4\ \text{CO}_2 + 5\ \text{H}_2\text{O}
\end{array}$$

The carbon dioxide released during fatty acid utilization is thought to arise exclusively from the oxalacetate → phosphoenolpyruvate step and thus a maximum of 75 per cent of the carbon atoms in the entering acetyl units may be converted to sucrose. Values of more than 50 per cent conversion with C-2 contributing twice as much as C-1 have in fact been observed experimentally. The gm.-for-gm. conversion of fat to sucrose is accounted for, as well as the *RQ* of 0·35 observed with endosperm slices. It should be emphasized that the quantitative agreement between the predictions of the sequence and the physiological features of the fat–carbohydrate conversion indicate that metabolism by way of the glyoxylate cycle is the fate of all of the acetate produced. The overall efficiency is such that very little must pass through the decarboxylative steps of the tricarboxylic acid cycle or be drained off in other reactions. Feeding experiments with pyruvate and acetate show that glutamate (α-ketoglutarate) production accounts for only a very small fraction of the acetate carbon utilized.

The limited distribution of the malate synthetase and isocitratase, the increasing activity and subsequent declines which they show in synchrony with the pace of fat breakdown during germination, indicate that the importance of the glyoxylate cycle in higher plants may well be confined to the part it plays during the early stages of germination of fatty seedlings.

KURT LIDÉN and RICHARD C. McCALL

Radiation Physics Department, University of Lund, Sweden

As a result of nuclear weapons tests, large amounts of fission products have been introduced into the atmosphere. Up to the end of 1958 more than 250 test explosions had taken place and fission materials equivalent to 92 MT TNT had been released[1].

The fission products, once introduced into the troposphere and stratosphere, have in turn given rise to a world-wide surface deposition of isotopes. The contamination of plants and soil with these isotopes has, either directly or through selective uptake, made these isotopes available in the human diet and in the human body itself.

Among the various isotopes present in fall-out, strontium-90 and cæsium-137 are of special interest due to their long half-lives, their relatively high fission yields and similarities to important body constituents. Strontium-90 is chemically and metabolically related to calcium and must therefore be classified as a bone-seeker, while cæsium-137 behaves similarly to potassium and concentrates mainly in the muscle, liver and spleen.

The introduction of cæsium-137 into the biosphere has received considerable attention, and the mechanism of uptake of this isotope from soil through plants and animals has been discussed in detail in an effort

to evaluate the relationship between body burdens in man and deposition of fall-out[2]. Several uncertainties seem to exist, among them the discrimination factor of cæsium-137 relative to potassium through the food chain and the rate of elimination of cæsium from the body.

The presence of cæsium-137 in various foodstuffs and also in human beings has been reported by several investigators[3-6]. Since cæsium-137 is a γ-emitter, its radiation can be detected in bulk materials by ordinary γ-spectroscopic means. Heavily shielded scintillation counters in connexion with multichannel analysers are mainly used for that purpose, and measurements of content of cæsium-137 in man are at present being made in the United States, Sweden, Britain, Germany, Canada and France.

Due to the chemical similarity between cæsium and potassium it is usual to state the concentration of cæsium-137 relative to potassium in the body. This partially eliminates effects due to differences in body-weights and simplifies comparison of body-burdens in different subjects. The results, usually expressed as pc. cæsium-137/gm. potassium to-day show a mean value of approximately 50 for persons without any occupational exposure to cæsium-137 in the countries mentioned. However, reports have been published on special cases where this number has been found to be considerably higher. In connexion with the Windscale accident, a value of 443 pc./gm. potassium was reported with a pre-accident value of 107 (ref. 7). At Hanford, an off-site visitor was found to have a cæsium-137 content of 66 nc. and a cæsium-137/potassium ratio of 370 (ref. 8). This was traced to an extremely unusual diet and milk source.

Comparison between values for the cæsium-137 content of individuals measured at different laboratories might be open to question. Agreement between different laboratories on the standardization of point sources is not always good. Recently[9] comparison of a group of so-called standard sources from several countries showed a spread of about 20 per cent although each of the sources was supposed to be standardized to ± 5 per cent or better. In comparing measurements at various times, it should be kept in mind that the cæsium-137 body-burden was increasing until some time in the middle of 1959 and has been decreasing since.
